**THE PRINCIPLES AND
PRACTICE OF MEDICINE**

THE PRINCIPLES AND PRACTICE OF MEDICINE

*DESIGNED FOR THE USE OF PRACTITIONERS AND
STUDENTS OF MEDICINE*

ORIGINALLY WRITTEN BY

THE LATE SIR WILLIAM OSLER, BT., M.D., F.R.S.

FORMERLY FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS, LONDON; REGIUS PROFESSOR OF
MEDICINE, OXFORD UNIVERSITY; HONORARY PROFESSOR OF MEDICINE, JOHNS HOPKINS
UNIVERSITY, BALTIMORE; PROFESSOR OF THE INSTITUTES OF MEDICINE, MCGILL
UNIVERSITY, MONTREAL, AND PROFESSOR OF CLINICAL MEDICINE IN
THE UNIVERSITY OF PENNSYLVANIA, PHILADELPHIA

ELEVENTH EDITION REVISED BY

THOMAS McCRAE, M.D.

FELLOW OF THE ROYAL COLLEGE OF PHYSICIANS, LONDON; PROFESSOR OF MEDICINE, JEFFERSON
MEDICAL COLLEGE, PHILADELPHIA; PHYSICIAN TO THE JEFFERSON AND PENNSYLVANIA
HOSPITALS, PHILADELPHIA; FORMERLY ASSOCIATE PROFESSOR
OF MEDICINE, JOHNS HOPKINS UNIVERSITY

NEW YORK AND LONDON
D. APPLETON AND COMPANY

TO THE
Memory of Three Teachers of William Osler:

WILLIAM ARTHUR JOHNSON
PRIEST OF THE PARISH OF WESTON, ONTARIO

JAMES BOVELL
OF THE TORONTO SCHOOL OF MEDICINE, AND OF THE
UNIVERSITY OF TRINITY COLLEGE, TORONTO

ROBERT PALMER HOWARD
DEAN OF THE MEDICAL FACULTY AND PROFESSOR OF MEDICINE,
MCGILL UNIVERSITY, MONTREAL

PREFACE

THE Osler Textbook has had a wide distribution, well over a quarter of a million copies having been sold since the first printing in 1892. In this revision, as before, every effort has been made to retain what is characteristic of William Osler in this textbook, which was one of the great interests of his life.

As in all revisions of medical books there is the frequent decision to be made as to how much of the new has earned the right to displace the old. A textbook must give a description of the average picture of disease and cannot devote too much space to a discussion of the exceptions. The student should be given an account of what can be regarded as well-established knowledge. The amount of space must be limited if the book is to be kept to a convenient size and it is a matter of nice judgment to hold the scales between the new and the old. No two men could always agree as to which part or how much of the old should give way to the new. Certain additions demand their place and one must decide as to what is to be deleted. To know to-day how much of the newer work will be of little value five years in the future and what will be established as useful is beyond human power always to decide correctly. For example, what is the importance of the bacteriophage in the treatment of certain infectious diseases? Then again, there is a great temptation to discuss certain points, such as the problems concerned with the action of insulin, but space does not permit.

There are questions which always demand careful thought. In the matter of arrangement, for example, should all the results of syphilis, such as aneurism, be placed under the heading of the disease or under the diseases of the system involved? Is infectious chorea better left with the diseases of the nervous system or placed with the infectious diseases? Is chlorosis deserving of mention or should it be dropped as a disease entity? The main consideration should be given to the student and the discussion made as clear as possible for him.

There is one problem which gives constant concern in the revision of a textbook, and that is to use correct terminology. The changes and variations in names are confusing to say the least. For example, what is the correct name for the organisms which cause the relapsing fevers? Four different works are consulted, all supposed to be authoritative, and the following designations given to the organism found: *Spirochæta*, *Borrelia*, *Spirochæta* and *Treponema*. The new designations given to various bacteria may come into general use some day. No marked signs are evident that the day is close at hand.

In this edition new subjects which have been added are: Melioidosis, Uveoparotid Fever, *Bacillus fecalis alkaligenes* Infection, Exanthema Subitum, Poisoning from Radio-active Substances, Poisoning from Arseniuretted

Hydrogen, Poisoning from Methyl Chloride, Hypoglycæmia, Asbestosis, Pentosuria, Subacute Leukæmia, Coronary Artery Aneurism, Macrogenitosomia Præcox, Myelophthisic Splenomegaly, Lipoid Histiocytosis, Post-vaccinal Encephalitis, Encephalitis Periaxialis Diffusa, Centro-lobar Cerebral Sclerosis, Osteitis Fibrosa Cystica, Albers-Schönberg Disease, Spondylolisthesis, Defects in Membranous Bones with Exophthalmos and Diabetes Insipidus, Hypophyseal Cachexia, and Hemiballismus. Considerable alterations or additions have been made to Undulant Fever, Diabetes Mellitus (including the use of Synthalin), Duodenitis, Cardiospasm (Phrenospasm), Hæmorrhagic Nephritis, Nephrosis, Nephritis in general, Purpura (the various forms), Paroxysmal Cardiac Dyspnoea, Infantile Splenic Anæmia, Glosso-pharyngeal Neuralgia, and Compression Fractures of the Spine. There are many alterations throughout the work.

To my associates, Dr. E. H. Funk and Dr. H. K. Mohler, I am particularly indebted for assistance and advice, and Dr. B. L. Gordon and Dr. G. G. Duncan have aided me in the preparation of certain sections. To those who have written sending suggestions and constructive criticism, appreciation of their interest is due and cordially given.

THOMAS McCRAE.

PREFACE TO FIRST EDITION

My thanks are due to my former first assistant, H. A. Lafleur, for much help, direct and indirect; to his successor, W. S. Thayer, for assistance in the section on Blood Diseases and for the preparation of the illustrative charts; to D. Meredith Reese, for the statistics on tuberculosis; to H. M. Thomas, for many suggestions in the section on Nervous Diseases, and particularly in the section on Topical Diagnosis; to L. P. Powell, of the Johns Hopkins University Library, for a careful revision of the manuscript; and to Miss B. O. Humpton, for valuable aid, especially in the preparation of the index.

WILLIAM OSLER

Johns Hopkins Hospital
Baltimore, *January 1, 1892.*

“Experience is fallacious and judgment difficult.”

HIPPOCRATES: *Aphorisms, I.*

“And I said of medicine, that this is an art which considers the constitution of the patient, and has principles of action and reasons in each case.”

PLATO: *Gorgias.*

**THE PRINCIPLES AND
PRACTICE OF MEDICINE**

THE PRINCIPLES AND PRACTICE OF MEDICINE

SECTION I

SPECIFIC INFECTIOUS DISEASES

A. BACTERIAL DISEASES

I. TYPHOID FEVER

Definition.—A general infection caused by the *Bacillus typhosus*, characterized anatomically by hyperplasia and ulceration of the intestinal lymph-follicles, swelling of the mesenteric glands and spleen, and parenchymatous changes in the other organs. There are cases in which the local changes are slight or absent, and there are others with intense localization in the lungs, spleen, kidneys, or cerebro-spinal system. Clinically the disease is marked by fever, rose-colored eruption, abdominal tenderness, tympanites, and enlargement of the spleen; but these features are extremely inconstant, and even the fever varies in its character.

Historical Note.—Huxham, in his remarkable Essay on Fevers, had “taken notice of the great difference there is between the *putrid malignant* and the *slow nervous fever*.” In 1813 Pierre Bretonneau, of Tours, distinguished “*dothiéntérite*” as a separate disease; and Petit and Serres described enteromesenteric fever. In 1829 Louis’ great work appeared, in which the name “typhoid” was given to the fever. At this period typhoid fever alone prevailed in Paris and many European cities, and was universally believed to be identical with the continued fever of Great Britain, where in reality typhoid and typhus coexisted. The intestinal lesion was regarded as an accidental occurrence in ordinary typhus fever. Louis’ students, returning to their homes in different countries, had opportunities for studying the prevalent fevers in the thorough and systematic manner of their master. Among these were certain young American physicians, to one of whom, Gerhard, of Philadelphia, is due the great honor of having first clearly laid down the differences between the two diseases. His papers in the American Journal of the Medical Sciences, 1837, are the first which give a full and satisfactory account of their clinical and anatomical distinctions. The studies of James Jackson, Sr. and Jr., of Enoch Hale and of George C. Shattuck, of Boston, and of

Alfred Stillé and Austin Flint made the subject very familiar in American medicine. In 1842 Elisha Bartlett's work appeared, in which, for the first time in a systematic treatise, typhoid and typhus fever were separately considered with admirable clearness. In Great Britain the recognition of the difference between the two diseases was slow, and due largely to A. P. Stewart and Jenner. Eberth discovered the organism in 1880.

Etiology.—GENERAL PREVALENCE.—Typhoid fever prevails especially in temperate climates, in which it constitutes the most common continued fever. Widely distributed throughout all parts of the world, it presents everywhere the same essential characteristics, and is an index of the sanitary intelligence of a community. *Imperfect sewerage* and *contaminated water-supply* are two special conditions favoring the distribution of the bacilli, while from an infected person the disease may be spread by *flies*, *food* and *flies*.

In *England* and *Wales* in 1923 the disease was fatal to 450 persons, a mortality of 12 per million of living persons. It destroys more lives in proportion to population in towns than in the country. The rate was lower in 1923 than in any year since 1869. In the *United States* there has been a marked decrease, due largely to chlorination of the water-supplies. The death-rate per 100,000 population in the registration areas has fallen from 35.9 in 1900 to 6.7 in 1924, and 8 in 1925. In 1928 the death-rate in the seventy-four largest cities was 1.89 per 100,000. It is more prevalent in country districts than in cities, and, as Fulton showed, the propagation is largely from the country to the town.

Typhoid fever has been one of the great scourges of armies, and killed more than powder and shot. In the Spanish-American War the report of the Commission (Reed, Vaughan, and Shakespeare) showed that in the national encampments among 107,973 men there were 20,738 cases of typhoid fever with 1,580 deaths. In 90 per cent. of the volunteer regiments the disease broke out within eight weeks after going into camp. In the opinion of the Commission the most important factors were camp pollution, flies as carriers of contagion, and contamination through the air in the form of dust. In the South African War the British army, 557,653 officers and men, had 57,684 cases of typhoid fever, with 8,225 deaths (Simpson), while only 7,582 men died of wounds received in battle. The disease was essentially one of the standing camps; troops constantly on the move were rarely much affected. While contaminated water was no doubt an important factor, as it always is in camp pollution, yet certain of the conditions in Africa were peculiar. Fæcal and urinary contamination must have been very common, as in the cooking, performed in the open air, sand "entered largely into every article of food." As there was a plague of flies, they were a factor in the infection of both food and drink. In the great European war typhoid fever did not prevail to any extent in the Western armies and the efficacy of inoculation was thoroughly demonstrated. The large proportion of paratyphoid cases was remarkable.

Season.—Almost without exception the disease is everywhere more prevalent in the autumn, hence the old popular name autumnal fever. The study by Sedgwick and Winslow shows everywhere a striking parallelism between the monthly variations in temperature and the prevalence of the disease. In a few cities the curves were irregular, showing, in addition to the usual sum-

mer rise, two secondary maxima in the winter and spring, and these authors suggest that epidemics at these seasons are characteristic of cities whose water-supply is most subject to pollution. In their opinion "the most reasonable explanation of the seasonal variations of typhoid fever is a direct effect of the temperature upon the persistence in nature of the germs which proceed from previous victims of the disease."

Of 1,500 cases at the Johns Hopkins Hospital (upon the study of which this section is based), 840 were in August, September, and October.

Sex.—Males and females are equally liable to the disease, but males are much more frequently admitted into hospitals, 2.4 to 1 in our series.

Age.—Typhoid fever is a disease of youth and early adult life. The greatest susceptibility is between the ages of fifteen and twenty-five. Of the 1,500 cases there were under fifteen years of age, 231; between fifteen and twenty, 253; between twenty and thirty, 680; between thirty and forty, 227; between forty and fifty, 88; between fifty and sixty, 8; above sixty, 11; age not given, 1. Cases in advanced life are not uncommon, but as the course is often atypical the diagnosis may be uncertain and the disease not recognized until autopsy. It is not infrequent in childhood, but infants are rarely attacked. Murchison saw a case at the sixth month.

Immunity.—Not all exposed to infection contract the disease. After recovery the immunity is apparently permanent but only against the particular infecting organism; infection with the typhoid bacillus does not protect against paratyphoid infections and *vice versa*. In 500 of our cases in which special inquiry was made as to a previous attack it was found to have occurred in 2.2 per cent. The interval varied from nine months to thirty years. Usually within a short time after recovery the immune substances disappear from the blood, yet in most cases the immunity lasts for life. An experimental explanation for this fact has been given in the demonstration that animals which have once reacted to the typhoid infection, react in throwing out immune substances more quickly and in larger amounts when danger again threatens (Cole).

BACILLUS TYPHOSUS.—(a) *General Characters.*—It is a rather short, thick, flagellated, motile bacillus, with round ends, about 3μ in length and 0.6μ in breadth. This organism fulfills all the requirements of Koch's law—it is constantly present, and grows outside the body in a specific manner; the third requirement, the production of the disease experimentally, has been met by its conveyance to chimpanzees. The disease has resulted from the swallowing of cultures with suicidal intent. The bacilli or their toxins inoculated in large quantities into the blood of rabbits are pathogenic, and in some instances ulcerative and necrotic lesions in the intestine may be produced. But similar intestinal lesions may be caused by other bacteria, including *Bacillus coli*.

Cultures are killed within ten minutes by a temperature of 60° C. They may live for eighteen weeks at -5° C., although most die within two weeks, and all within twenty-two weeks (Park). The typhoid bacillus resists ordinary drying for months, unless in very thin layers, when it is killed in five to fifteen days. The direct rays of the sun completely destroy them in from four to ten hours' exposure. Bouillon cultures are destroyed by carbolic acid, 1 to 200, and by corrosive sublimate, 1 to 2,500.

(b) *Distribution in the Body.*—The bacilli are probably in the circulating blood in the early stages of the disease in all cases. During life they may be

demonstrated in the blood in a large proportion of cases, in 75 per cent. of 604 collected cases (Coleman and Buxton). They occur in the urine in from 25 to 30 per cent. of the cases (if hexamine is not given). They may be isolated from the stools in practically all cases at some stage. They are probably always present in the rose spots. They are reported to have been cultivated from the sweat, and occur with considerable frequency in the sputum (Richardson, Rau, and others). They have been found in the milk of nursing women. At autopsy they are found widely distributed, most numerous and constant usually in the mesenteric glands, spleen, and gall-bladder, but are found in almost all organs, even the muscles, uterus, and lungs (von Drigalski). Cultures made from the intestines at autopsy show that they are very numerous in the duodenum and jejunum, and practically constant in cultures made from the mucous membrane of the stomach. They are present in the oesophagus and frequently on the tongue and tonsils. From endocardial vegetations, from meningeal and pleural exudates and from foci of suppuration in various parts of the body, the bacilli have been isolated. A most important fact is that they may be present in the stools of persons who show no symptoms of typhoid fever, but who have lived in very close association with typhoid-fever patients. This is especially true of children.

(c) *The Bacilli outside the Body.*—In sterile water the bacilli retain their vitality for weeks, but under ordinary conditions, in competition with saprophytes, disappear within a few days. The question of the longevity of the typhoid bacillus in water is of great importance, and was much discussed in connection with the supposed pollution of the water of the Mississippi by the Chicago drainage canal. The experiments of E. O. Jordan indicated that the vitality was retained as a rule not longer than three days after infection. Whether an increase can occur in water is not finally settled. Their detection in water is difficult, and although they undoubtedly have been found, many discoveries are not certain on account of inaccurate differentiation. Newer methods have been successful in obtaining positive growth from sewage. Both Prudden and Ernst found it in water filters.

Sedgwick and Winslow concluded from their study that very few typhoid germs survive in ice. The Ogdensburg epidemic in 1902-'03 was apparently due to infection from ice. Typhoid bacilli were grown from frozen material in it (Hutchins and Wheeler).

In milk the bacilli undergo rapid development without changing its appearance. They may persist for three months in sour milk, and may live for several days in butter made from infected cream.

Robertson has shown that under entirely natural conditions typhoid bacilli may live in the upper layers of the soil for eleven months. In stools which contain typhoid bacilli, kept at room temperature, the *B. typhosus* disappears in a few days.

The direct infection of exposed food-stuffs by dust is very probable. The bacilli retain their vitality for many weeks; in garden earth 21 days, in filter-sand 82 days, in street dust 30 days, on linen 60 to 70 days, on wood 32 days, on thread kept under suitable conditions for a year.

MODES OF CONVEYANCE.—(a) The essential fact is that organisms from a patient with the disease or from a carrier are taken in by a healthy individual. The methods of conveyance are many; it may be direct from

the patient to an attendant; food may be infected by an attendant; flies may carry the bacilli and infect food; or a water supply may be infected by the excreta. A carrier is always a source of danger, especially if handling food. Fingers, food and flies are the chief means of local propagation. Every patient is a possible source of infection. It is impossible for a nurse to avoid finger contamination, and without scrupulous care the germs may be distributed. Even with special precautions and an unusually large proportion of nurses to patients, it was not possible to avoid "house" infection at the Johns Hopkins Hospital. T. B. Futcher analyzed 30 cases contracted in the hospital among the first 1,500 cases; physicians, 5¹ among a total of 288; nurses, 15 of a total of 407; patients, 8 out of a total of 47,956 admissions; 4 of these occurred in a small ward epidemic. Two orderlies were infected while caring for typhoid patients.

(b) Infection of water is the most common source of widespread epidemics, many of which have originated in the contamination of a well or spring. A striking one occurred at Plymouth, Pa., in 1885. The town, with a population of 8,000, was in part supplied with drinking-water from a reservoir fed by a mountain stream. During January, February, and March, in a cottage by the side of and at a distance of from 60 to 80 feet from this stream, a man was ill with typhoid fever. The attendants were in the habit at night of throwing out the evacuations on the ground toward the stream. During these months the ground was frozen and covered with snow. In the latter part of March and early in April there was considerable rainfall and a thaw, in which a large part of the three months' accumulation of discharges was washed into a brook, not 60 feet distant. At the time of this thaw the patient had numerous and copious discharges. About the 10th of April cases of typhoid fever broke out in the town, appearing for a time at the rate of 50 a day. In all about 1,200 people were attacked. An immense majority of all the cases were in the part of the town which received water from the infected reservoir.

(c) Typhoid Carriers.—The bacilli may persist indefinitely in the bile passages and intestines of persons in good health. They have been found in the urinary bladder and in the gall-bladder, twenty and thirty years after the fever, and there have been cases of typhoid bone lesion from which the bacilli were isolated many years after the primary attack. The work of Strassburg observers called attention to a group of chronic typhoid carriers of the first importance in the spread of the disease, the majority of whom are females. Many localized epidemics have been traced to carriers. Soper reported an instance in which a cook, apparently in perfect health, but in whose stools bacilli were present in large numbers, had been responsible for the occurrence of typhoid in seven households in five years. There is no limit to the length of time in which the bacilli may persist. One carrier had the attack of typhoid fever forty-seven years before. The paratyphoid bacillus may be carried in the same way. An epidemic of 19 cases in a French barrack was traced to a cook.

(d) Infection of Food.—Milk may be the source of infection. The milk may be contaminated by infected water used in cleaning the cans or by carriers or those nursing typhoid patients. The milk epidemics have been col-

¹Only three of these were in attendance on typhoid cases. Two of the five died—Oppenheimer and Ochsner.

lected by Ernest Hart and by Kober. The germs may be conveyed in ice, salads of various sorts, spaghetti, etc. The danger of eating celery and other uncooked vegetables, which have grown in soil on which infected material has been used as a fertilizer, must not be forgotten.

Much attention has been paid to the *oyster* as a source of infection, but it plays a very small relative part. In several epidemics, such as that in Middletown, reported by Conn, that in Naples, by Lavis, and the outbreak at Winchester, the chain of circumstantial evidence seems complete. Foote showed that oysters taken from the feeding-grounds in rivers contain a larger number of microorganisms of all sorts than those from the sea. Chantemesse found typhoid bacilli in oysters which had lain in infected sea-water, even after they had been transferred to and kept in fresh water for a time. Mussels have been found contaminated with typhoid bacilli, and it is stated that dried fish have carried the infection.

(e) *Flies*.—The importance of flies in the transmission of the disease was brought out very strongly in the Spanish-American War in 1898. The Report of the commission states that “flies were undoubtedly the most active agents in the spread of typhoid fever. Flies alternately visited and fed on the infected faecal matter and the food in the mess-tent. . . . Typhoid fever was much less frequent among members of the messes who had their mess-tents screened than it was among those who took no such precautions.” Firth and Horrocks demonstrated the readiness with which flies, after feeding on typhoid stools or fresh cultures of typhoid bacilli, could infect sterile media. One of the most interesting studies was made in the Chicago epidemic of 1902 by Alice Hamilton. Flies caught in two undrained privies, on the fences of two yards, on the walls of two houses, and in the room of a typhoid fever patient, were used to inoculate eighteen tubes, and from five of these tubes typhoid bacilli were isolated.

(f) *Contamination of the Soil*.—This is important if water supplies are infected as a result. Filth, bad sewers, or cesspools can not in themselves cause typhoid fever, but they furnish the conditions suitable for the preservation of the bacillus, and possibly for its propagation. Dust may be an important factor, though the bacilli usually die quickly when desiccated.

TYPES OF INFECTION.—We may recognize the following groups: (a) *Ordinary typhoid fever with marked enteric lesions.* An immense majority of all cases are of this character; and while the spleen and mesenteric glands are involved the lymphatic apparatus of the intestinal walls bears the brunt of the attack. (b) *Cases in which the intestinal lesions are very slight,* and may be found only after a very careful search. In reviewing the cases of “typhoid fever without intestinal lesions,” Opie and Bassett call attention to the fact that in many negative cases slight lesions really did exist, while in others death occurred so late that the lesions might have healed. In some cases the disease is a general septicæmia with severe intoxication, high fever and delirium. In others the main lesions may be in organs—liver, gall-bladder, pleura, meninges, or even the endocardium. (c) *Cases in which the typhoid bacillus enters the body without causing any lesion of the intestine.* In a number of the earlier cases reported as such the demonstration of the typhoid bacillus was inconclusive. In others the intestine showed tuberculous ulcers, through which the organisms may have entered. But after excluding

these, a few cases remain in which the demonstration of the typhoid bacillus was conclusive, cases in which death occurred early, and yet no intestinal lesions could be found. There were 4 cases in this series. Undoubtedly the intestinal lesions may be so slight as not to be recognizable at autopsy. (d) Mixed infections. It is well to distinguish between double infections, as typhoid fever with tuberculosis, diphtheria or malaria, in which two different diseases are present, and the true mixed or secondary infections, in which the conditions induced by one organism favor the growth of other pathogenic forms; thus in typhoid fever secondary infection with the colon bacillus, streptococcus, staphylococcus, or pneumococcus, may occur. (e) Paratyphoid infections. (Page 42.) (f) Local infections. The typhoid bacillus may cause a local abscess, cystitis, or cholecystitis without evidence of a general infection. (g) Terminal typhoid infections. In rare instances the bacillus causes a fatal infection towards the end of other diseases. The subjects may, of course, be typhoid carriers. In two cases of malignant disease at the Johns Hopkins Hospital the bacilli were isolated from the blood, and there were no intestinal lesions.

Products of the Growth of the Bacilli.—According to Pfeiffer, the chief poison belongs to the intracellular group of toxins. Sidney Martin isolated a poison which is in the nature of a secretion, but does not differ from that contained within the bacterial cell. Injected into animals it causes lowering of temperature, diarrhœa, loss of weight, and degeneration of the myocardium. Its chemical nature is not known. Similar, but weaker, poisons may be isolated from cultures of *Bacillus coli* and other members of this group. No toxins have been isolated which cause changes in animals at all comparable to typhoid fever in human beings.

Morbid Anatomy.—INTESTINES.—A catarrhal condition exists throughout the small and large bowel. Specific changes occur in the lymphoid elements, chiefly at the lower end of the ileum. The alterations which occur are most conveniently described in four stages:

(a) Hyperplasia, which involves the glands of Peyer in the jejunum and ileum, and to a variable extent those in the large intestine. The follicles are swollen, grayish-white, and the patches may project 3 to 5 mm. The solitary glands, which range in size from a pin's head to a pea, are usually deeply imbedded in the submucosa, but project to a variable extent. Occasionally they are very prominent, and may be almost pedunculated. Microscopic examination shows at the outset a condition of hyperæmia of the follicles. Later there is a great increase and accumulation of cells of the lymph-tissue which may even infiltrate the adjacent mucosa and the muscularis; and the blood-vessels are more or less compressed, which gives the whitish, anæmic appearance to the follicles. The cells have all the characters of ordinary lymph-corpuscles, but some are larger, epithelioid, and contain several nuclei. Occasionally cells containing red blood corpuscles are seen. The so-called medullary infiltration, always more intense toward the lower end of the ileum, reaches its height from the eighth to the tenth day and then undergoes one or two changes, resolution or necrosis. Death very rarely takes place at this stage. Resolution is accomplished by a fatty and granular change in the cells, which are destroyed and absorbed. A curious condition of the patches is produced at this stage, in which they have a reticulated appearance.

The swollen follicles in the patch undergo resolution and shrink more rapidly than the surrounding framework, or what is more probable the follicles alone, owing to the intense hyperplasia, become necrotic and disintegrate, leaving the little pits. In this process superficial hæmorrhages may result, and small ulcers may originate by the fusion of these superficial losses of substance.

Except histologically there is nothing distinctive in the hyperplasia of the lymph-follicles; but apart from typhoid fever we rarely see in adults a marked affection of these glands with fever. In children, however, it is not uncommon when death has occurred from intestinal affections, and it is also met with in measles, diphtheria, and scarlet fever.

(b) *Necrosis and Sloughing*.—When the hyperplasia of the lymph-follicles reaches a certain grade, resolution is no longer possible. The blood-vessels become choked, there is anæmic necrosis, and sloughs form which must be separated. The necrosis is probably due in great part to the direct action of the bacilli. According to Mallory, there occurs a proliferation of endothelial cells due to the action of a toxin. These cells are phagocytic, and the swelling of the intestinal lymphoid tissue is due almost entirely to their formation. The necrosis, he thinks, is due to the occlusion of the veins and capillaries by fibrinous thrombi, which owe their origin to degeneration of phagocytic cells beneath the lining endothelium of the vessels. The process may be superficial, affecting only the upper part of the mucous coat, or it may extend to and involve the submucosa. The “slough” may sometimes lie upon the Peyer’s patch, scarcely involving more than the epithelium (Marchand). It is always more intense toward the ileo-cæcal valve, and in very severe cases the greater part of the mucosa of the last foot of the ileum may be converted into a brownish-black eschar. The necrotic area in the solitary glands forms a yellowish cap which often involves only the most prominent point of a follicle. The extent of the necrosis is very variable. It may pass deep into the muscular coat, reaching to or even perforating the peritoneum.

(c) *Ulceration*.—The separation of the necrotic tissue—the sloughing—is gradually effected from the edges inward, and results in the formation of an ulcer, the size and extent of which are directly proportionate to the amount of necrosis. If this be superficial, the entire thickness of the mucosa may not be involved and the loss of substance may be small and shallow. More commonly the slough in separating exposes the submucosa and muscularis, particularly the latter, which forms the floor of a majority of all typhoid ulcers. It is not common for an entire Peyer’s patch to slough away, and a perfectly ovoid ulcer opposite to the mesentery is rarely seen. Irregularly oval and rounded forms are most common. A large patch may present three or four ulcers divided by septa of mucous membrane. The terminal 6 or 8 inches of the ileum may form a large ulcer, in which are here and there islands of mucosa. The edges of the ulcer are usually swollen, soft, sometimes congested, and often undermined.

(d) *Healing*.—This begins with the development of a thin granulation tissue which covers the base. Occasionally it seems as if an ulcer had healed in one place and was extending in another. The mucosa gradually extends from the edge, and a new growth of epithelium is formed. The glandular elements are re-formed; the healed ulcer is somewhat depressed and is usually pigmented. In death during relapse healing ulcers may be seen in some patches

with fresh ulcers in others. Healing begins with the separation of the sloughs, as, when resolution is impossible, the removal of the necrosed part is the first step in the process of repair. In fatal cases, we seldom find evidences of cicatrization, as the majority of deaths occur before this stage is reached. It is remarkable that no matter how extensive the ulceration has been, healing is never associated with stricture, and typhoid fever is not one of the causes of intestinal obstruction. Within a very short time all traces of the old ulcers disappear.

LARGE INTESTINE.—The cæcum and colon are affected in about one-third of the cases. Sometimes the solitary glands are greatly enlarged. The ulcers are usually larger in the cæcum than in the colon.

PERFORATION OF THE BOWEL.—*Incidence at Autopsy.*—J. A. Scott's figures, embracing 9,713 cases, give 351 deaths from perforation among 1,037 deaths from all causes, a percentage of 33.8 of the deaths and 3.6 of the cases. The German statistics give a much lower proportion of deaths from perforation; Munich in 2,000 autopsies, 5.7 per cent. from perforation; Basle in 2,000 autopsies, 1.3 per cent. from perforation; Hamburg in 3,686 autopsies, 1.2 per cent. from perforation (Hector Mackenzie, *Lancet*, 1903). At the Johns Hopkins Hospital among 1,500 cases of typhoid fever there were 43 with perforation. Twenty of these were operated upon, with 7 recoveries. One died of toxæmia on the eighth day after operation. At the Pennsylvania Hospital there were 139 cases of perforation among 5,891 cases. Chomel remarks that "the accident is sometimes the result of ulceration, sometimes of a true eschar, and sometimes it is produced by the distention of the intestine, causing the rupture of tissues weakened by disease." The site is usually in the ileum, 232 times in Hector Mackenzie's collection of 264 cases; the jejunum twice, the large intestine 22 times, and the appendix 9 times in his series. As a rule, the perforation occurs within twelve inches of the ileo-cæcal valve. There may be two or three separate perforations. Scott described two distinct varieties: first, the more common single, circular, pin-point in size, due to the extension of a necrotic process through the base of a small ulcer. The second variety, produced by a large area of tissue becoming necrotic, ranges in size from the finger-tip to 3 cm. in diameter.

Death from hæmorrhage occurred in 99 of the Munich cases, and in 12 of 137 deaths in our 1,500 cases. The bleeding seems to result directly from the separation of the sloughs. It is unusual to find the bleeding vessel. In one case only a single patch had sloughed, and a firm clot was adherent to it. The bleeding may come from the soft swollen edges of the patch.

The mesenteric glands show hyperæmia and subsequently become greatly swollen. Spots of necrosis are common. In several of our cases suppuration occurred, and in one a large abscess of the mesentery was present. The rupture of a softened or suppurating mesenteric gland, of which there are only a few cases in the literature, may cause fatal hæmorrhage or peritonitis. Le Conte successfully operated upon the latter condition. The bunch of glands in the mesentery, at the lower end of the ileum, is especially involved. The retroperitoneal glands are also swollen.

The spleen is invariably enlarged in the early stages. In 11 of our series it exceeded 600 grams in weight, in one 900 grams. The tissue is soft, even diffuent. Infarction is not infrequent. Rupture may occur spontaneously

or as a result of injury. In the Munich autopsies there were 5 instances of rupture of the spleen, one from a gangrenous abscess.

The bone-marrow shows changes very similar to those in the lymphoid tissues and there may be foci of necrosis (Longcope).

The liver shows parenchymatous degeneration. Early in the disease it is hyperæmic, and in a majority of instances it is swollen, somewhat pale, on section turbid, and microscopically the cells are granular and loaded with fat. Nodular areas (microscopic) occur in many cases, some being lymphoid, others necrotic. In 12 of the Munich autopsies liver abscess was found, and in 3, acute yellow atrophy. In 3 of this series liver abscess occurred. Pylephlebitis may follow abscess of the mesentery or perforation of the appendix. Affections of the gall-bladder are not uncommon.

KIDNEYS.—Cloudy swelling with granular degeneration of the cells of the convoluted tubules, less commonly an acute nephritis, may be present. Rayer, Wagner, and others described the occurrence of numerous small areas infiltrated with round cells, which may have the appearance of lymphomata, or may pass on to softening and suppuration, producing the so-called *miliary abscesses*, of which there were 7 cases in this series. The typhoid bacilli have been found in these areas. The kidneys in cases of typhoid bacilluria may show no changes other than cloudy swelling. Diphtheritic inflammation of the pelvis of the kidney may occur. It was present in 3 of our cases, in one of which the tips of the papillæ were also affected. Catarrh of the bladder is not uncommon and diphtheritic inflammation may also occur.

RESPIRATORY ORGANS.—Ulceration of the larynx occurs in a certain number of cases; in the Munich series it was noted 107 times. It occurs in the posterior wall, at the insertion of the cords, at the base of the epiglottis, and on the ary-epiglottidean folds. The cartilages are very apt to become involved. In the later periods ulcers may be present.

Œdema of the glottis was present in 20 of the Munich cases, in 8 of which tracheotomy was performed. Diphtheritis of the pharynx and larynx is not very uncommon. It occurred in a most extensive form in 2 of our cases. Lobar pneumonia may be found early (see Pneumo-typhus), or it may be a late event. Hypostatic congestion and the condition of the lung spoken of as splenization occur. Gangrene of the lung occurred in 40 cases in the Munich series; abscess of the lung in 14; hemorrhagic infarction in 129. Pleurisy is not a common event. Fibrinous pleurisy occurred in about 6 per cent. of the Munich cases, and empyema in nearly 2 per cent.

CHANGES IN THE CIRCULATORY SYSTEM.—*Heart Lesions.*—Endocarditis, while not common, is probably more frequent than is generally supposed. It was present without being suspected in 3 out of 105 autopsies in this series, while in 3 other cases the clinical symptoms suggested its presence. Typhoid bacilli have been found in the vegetations. Pericarditis was present in 14 cases of the Munich autopsies. Myocarditis is not very infrequent. In protracted cases the muscle-fibre is usually soft, flabby, and of a pale yellowish-brown color. The softening may be extreme, though rarely of the grade described by Stokes in typhus fever, in which, when held apex up by the vessels, the organ collapsed over the hand, forming a mushroom-like cap. Microscopically, the fibres may show little or no change, even when the impulse of the heart has been extremely feeble. A granular parenchymatous

degeneration is common. Fatty degeneration may be present, particularly in long-standing cases with anæmia. The hyaline change is not common.

Lesions of the Blood-vessels.—Changes in the arteries are not infrequent. In 21 of 52 cases in our series, in which there were notes on the state of the aorta, fresh endarteritis was present, and in 13 of 62 cases in which the condition of the coronary arteries was noted similar changes were found (Thayer). Arteritis of a peripheral vessel with thrombus formation is not uncommon. Bacilli have been found in the thrombi. The artery may be blocked by a thrombus of cardiac origin—an embolus—but in the great majority of instances they are autochthonous and due to arteritis, obliterating or partial. Thrombosis in the veins is very much more frequent than in the arteries, but is not such a serious event. It is most frequent in the femoral, and in the left more often than the right.

NERVOUS SYSTEM.—There are very few obvious changes met with. Meningitis is rare and occurred in only 11 of the 2,000 Munich cases. The exudation may be serous, sero-fibrinous, or purulent, and typhoid bacilli have been isolated. Five cases of serous and one of purulent meningitis occurred in our series (Cole). Optic neuritis, which occurs sometimes in typhoid fever, has not been described in connection with the meningitis. The anatomical lesion of the aphasia—seen not infrequently in children—is not known; possibly it is an encephalitis. Parenchymatous changes have been met with in the peripheral nerves, and appear to be not very uncommon, even when there have been no symptoms of neuritis.

The voluntary muscles show, in certain instances, the changes described by Zenker, which occur in all long-standing febrile affections, and are not peculiar to typhoid fever. The muscle substance undergoes either a granular degeneration or a hyaline transformation. The abdominal muscles, the aductors of the thighs, and the pectorals are most commonly involved. Rupture of a rectus abdominis has been found post mortem. Hæmorrhage may occur. Abscesses may develop in the muscles during convalescence.

Symptoms.—In a disease as complex as typhoid fever it will be well first to give a general description, and then to study more fully the symptoms, complications, and sequelæ according to the individual organs.

GENERAL DESCRIPTION.—The period of incubation lasts from “eight to fourteen days, sometimes twenty-three” (Clinical Society), during which there are feelings of lassitude and inaptitude for work. The average is about ten days. The onset is rarely abrupt. In the 1,500 cases chills occurred at onset in 334, headache in 1,117, anorexia in 825, diarrhœa in 516, epistaxis in 323, abdominal pain in 443, constipation in 249, pain in right iliac fossa in 10. The patient at last takes to his bed, from which event, in a majority of cases, the definite onset may be dated. During the first week there is, in some cases (but by no means in all, as has long been taught), a steady rise in the fever, the evening record rising a degree or a degree and a half higher each day, reaching 103° or 104°. The pulse is not rapid when compared with the temperature, full in volume, but of low tension and often dicrotic; the tongue is coated and white; the abdomen is slightly distended and tender. Unless the fever is high there is no delirium, but the patient complains of headache, and there may be mental confusion at night. The bowels may be constipated or there may be loose movements often due to purgation.

Headache

Toward the end of the week the spleen becomes enlarged and the rash appears in the form of rose-colored spots, seen first on the skin of the abdomen. Cough and bronchitic symptoms are common at the outset.

In the *second week*, in cases of moderate severity, the symptoms become aggravated; the fever remains high and the morning remission is slight. The pulse is rapid and loses its dicrotic character. There is no longer headache, but there are mental torpor and dullness. The face looks heavy; the lips are dry; the tongue, in severe cases, becomes dry also. The abdominal symptoms, if present—diarrhœa, tympanites, and tenderness—become aggravated. Death may occur during this week, with pronounced nervous symptoms, or, toward the end of it, from hæmorrhage or perforation. In mild cases the temperature declines, and by the fourteenth day may be normal.

In the *third week*, in cases of moderate severity, the pulse ranges from 110 to 130; the temperature shows marked morning remissions, and there is a gradual decline in the fever. The loss of flesh is more noticeable, and the weakness pronounced. Diarrhœa and meteorism may occur for the first time. Unfavorable symptoms at this stage are the pulmonary complications, increasing feebleness of the heart, and pronounced delirium with muscular tremor. Special dangers are perforation and hæmorrhage.

With the *fourth week*, in a majority of instances, convalescence begins. The temperature gradually reaches the normal point, the tongue cleans, and the desire for food returns. In severe cases the fourth and even the fifth week may present an aggravated picture of the third; the patient grows weaker, the pulse is more rapid and feeble, the tongue dry, and the abdomen distended. He lies in a condition of profound stupor, with low muttering delirium and subsultus tendinum, and passes the fæces and urine involuntarily. Failure of the circulation and secondary complications are the chief dangers of this period.

In the *fifth and sixth weeks* protracted cases may still show irregular fever, and convalescence may not set in until after the fortieth day. In this period we meet with relapses in the milder forms or slight recrudescence of the fever. At this time, too, occur many of the complications and sequelæ.

SPECIAL FEATURES.—*Mode of Onset.*—As a rule, this is insidious, and the patient is unable to fix definitely the time at which he began to feel ill. The most important deviations from this common course are:

(a) *Onset with Pronounced, Sometimes Sudden, Nervous Manifestations.*—Headache, of a severe and intractable nature may be the initial symptom, or a severe facial neuralgia may for a few days put the practitioner off his guard. When the patients have kept about and, as they say, fought the disease, the first manifestation may be pronounced delirium. Such patients may leave home and wander about for days. In rare cases the disease sets in with the most intense cerebro-spinal symptoms, simulating meningitis—severe headache, photophobia, retraction of the head, twitching of the muscles, and even convulsions. Occasionally drowsiness, stupor, and signs of basilar meningitis may exist for days before the characteristic symptoms develop or the onset may be with mania and marked mental symptoms.

(b) *With Pronounced Pulmonary Symptoms.*—The initial bronchitis may be of great severity and obscure the other features of the disease. More striking still are those cases in which the disease sets in with a chill, with pain

in the side and all the characteristic features of lobar pneumonia or of acute pleurisy; or tuberculosis is suspected.

(c) *With Gastro-intestinal Symptoms.*—The incessant vomiting and pain may suggest acute gastro-enteritis or lead to a suspicion of poisoning, or the patient may be sent to the surgical wards for appendicitis.

(d) *With symptoms of an acute nephritis, smoky or bloody urine*, with much albumin and casts.

(e) *Ambulatory Form.*—Deserving of special mention are those cases in which the patient keeps about and attempts to work, or perhaps takes a long journey to his home. He may come under observation for the first time with a temperature of 104° or 105° , and the rash well out. Many of these cases run a severe course, and in general hospitals contribute largely to the mortality. Finally, there are rare instances in which typhoid is unsuspected until perforation or a profuse hæmorrhage from the bowels occurs.

FACIAL ASPECT.—Early in the disease the cheeks are flushed and the eyes bright. Toward the end of the first week the expression becomes more listless, and when the disease is well established the patient has a dull and heavy look. There is never the rapid anæmia of malarial fever, and the color of the lips and cheeks may be retained even to the third week.

FEVER—(a) *Regular Course* (Chart I).—In the stage of invasion the fever rises steadily during the first five or six days. The evening temperature is about a degree or a degree and a half higher than the morning remission, so that a temperature of 104° or 105° is not uncommon by the end of the first week. Having reached the height, the fever persists with very slight daily remissions. It may be singularly persistent and but little influenced by bathing or other measures. At the end of the second and throughout the third week the temperature becomes more distinctly remittent. The difference between the morning and evening record may be 3° or 4° , and the morning temperature may be normal. It falls by lysis, and the temperature is not considered normal until the evening record is at 98.4° .

(b) *Variations from the typical temperature curve* are common. We do not always see the gradual step-like ascent in the early stage; the patients do not often come under observation at this time. When the disease sets in with a chill, or in children with a convulsion, the temperature may rise at once to 103° or 104° . Defervescence may occur at the end of the second week and the temperature fall rapidly by crisis, reaching the normal within twelve or twenty hours. An inverse type of temperature, high in the morning and low in the evening, is occasionally seen, but has no special significance.

Sudden falls in the temperature may occur, thus, as shown in Chart II, a drop of 6.4° may follow an intestinal hæmorrhage, and the fall may be apparent before the blood has appeared in the stools. Sometimes during the anæmia which follows a severe hæmorrhage from the bowels there are remarkable oscillations in the temperature. Hyperpyrexia is rare. In only 58 of 1,500 cases did the fever rise above 106° . Before death the fever may rise; the highest we have known was 109.5° .

(c) *Post-typhoid Variations.*—(1) *Recrudescences.*—After a normal temperature of perhaps five or six days, the fever may rise suddenly to 102° or 103° , without constitutional disturbance, furring of the tongue, or abdominal symptoms. After persisting for two to four days the temperature falls.

Of 1,500 cases, 92 presented these elevations, notes of which are given in the *Studies on Typhoid Fever* (Johns Hopkins Hospital Reports). Constipation, errors in diet, or excitement may cause them. These attacks are a frequent source of anxiety; they are common, and it is not always possible to say upon what they depend. In some cases typhoid or colon bacilli are found in the blood. As a rule, if the rise in temperature is the result of a complication, such as thrombosis, there is an increase in the leucocytes. Naturally one suspects a relapse, but there is an absence of the step-like ascent, and, as a rule, the fever falls after a few days.

(2) The Sub-febrile Stage of Convalescence.—In children, in nervous patients, and in cases of anæmia, the evening temperature may keep up for weeks after the tongue has cleaned and the appetite has returned. This may usually be disregarded, and is often best treated by allowing the patient to get up, and by stopping the use of the thermometer. Of course, it is important not to overlook any latent complications.

(3) Hypothermia.—Low temperatures in typhoid fever are common, following baths, spontaneously in the third and fourth week in the periods of marked remissions, and following hæmorrhage. An interesting form is the persistent hypothermia of convalescence. For ten days or more, particularly in the protracted cases with great emaciation, the temperature may be 96.5° or 97°. It is of no special significance.

(d) The Fever of the Relapse.—This is a repetition in many instances of the original fever, a gradual ascent and maintenance for a few days at a certain height and then a decline. It is usually shorter than the original pyrexia, and rarely continues more than two or three weeks. (Chart I.)

(e) Afebrile Typhoid.—The occurrence of this is doubtful and the cases so termed are probably mild attacks with slight fever for a few days.

(f) Chills occur: (1) sometimes with the onset; (2) occasionally at intervals throughout the course, and followed by sweats (so-called sudoral form); (3) with complications, pleurisy, pneumonia, otitis media, phlebitis, etc.; (4) with active antipyretic treatment by the coal-tar remedies; (5) occasionally during the period of defervescence without any complication, sometimes due to a septic infection; (6) after the injection of vaccines or serum; (7) according to Herringham, chills may result from constipation. There are cases in which throughout the latter half of the disease chills recur with great severity. (See Chills in Typhoid Fever, *Studies II.*)

SKIN.—The characteristic rash consists of hyperæmic spots, which appear from the seventh to the tenth day, usually at first upon the abdomen. They are slightly raised, flattened papules, which can be felt distinctly, of a rose-red color, disappearing on pressure, and ranging in diameter from 2 to 4 mm. They were present in 93.2 per cent. of the white patients and 20.6 per cent. of the colored. They come out in successive crops, and after persisting for two or three days they disappear, occasionally leaving a brownish stain. The spots may be present upon the back and not upon the abdomen. The eruption may be abundant over the whole skin of the trunk, and on the extremities. There were 81 in which they occurred on the arms, 17 on the forearms, 43 on the thighs, legs 15, face 5, hands 3. The cases with very abundant eruption are not necessarily severe. Typhoid bacilli have been found in the spots. Sometimes the spots are capped by small vesicles. A profuse miliary

or sudaminal rash is not uncommon. In 38 cases in our series there were purpuric spots; 3 of the cases were true hæmorrhagic typhoid fever. The rash may not appear until the relapse. In 21 cases in our series the rose spots came out after the patient was afebrile.

A branny desquamation is not rare in children and common in adults after hydrotherapy. Occasionally the skin peels off in large flakes. A yellow color of the palms of the hands and soles of the feet is not uncommon.

Among other skin lesions the following may be mentioned:

Erythema.—It is not very uncommon in the first week of the disease to find a diffuse erythematous blush—*E. typhosum*. Sometimes the skin may have a peculiar mottled pink and white appearance. *E. exudativum*, *E. nodosum*, and urticaria may be present.

Herpes.—Herpes is rare in typhoid fever in comparison with its great frequency in malarial fever and in pneumonia. It was noted in 20 of our 1,500 cases, usually on the lips.

Skin Gangrene.—Areas of superficial gangrene may follow the prolonged use of an ice-bag. In children noma may occur; as reported by McFarland in the Philadelphia epidemic of 1898, there were many cases with multiple areas of gangrene of the skin. The nose, ears, and genitals may be attacked.

Sweats.—At the height of the fever the skin is usually dry. Profuse sweating is rare, but it is not very uncommon to see the abdomen or chest moist with perspiration. Sweats in some instances constitute a striking feature and may be associated with chilly sensations or actual chills. In this *sudoral* form there may be recurring paroxysms of chill, fever, and sweats (even several in twenty-four hours), and the case may be mistaken for malarial fever. Profuse sweats may occur with hæmorrhage or perforation.

Edema of the skin occurs: (1) As the result of vascular obstruction, most commonly of a vein, as in femoral thrombosis. (2) In connection with nephritis, very rarely. (3) In association with the anæmia and cachexia. The hair falls out after the attack, but complete baldness is rare. The nutrition of the nails suffers, and during and after convalescence transverse ridges may occur. A peculiar odor is exhaled from the skin in some cases. Whether due to a cutaneous exhalation or not, there is a very distinctive smell connected with many patients. Nathan Smith described it as of a "semi-cadaverous, musty character."

Lineæ atrophicae.—Lines of atrophy may appear on the skin of the abdomen, lateral aspects of the thighs and about the knees. They have been attributed to neuritis, and Duckworth reported a case in which the adjacent skin was hyperæsthetic.

Bed-sores are not uncommon in protracted cases, with great emaciation. In some cases the necrosis begins in the deeper structures but, as a rule, they result from pressure and are seen upon the sacrum, more rarely the ilia, the shoulders, and the heels. These are less common since the introduction of hydrotherapy and scrupulous care does much for their prevention, but in cases with profound toxæmia acute bed-sores may occur with very slight pressure, and with astonishing rapidity.

Boils and superficial abscesses constitute a common and troublesome sequel.

CIRCULATORY SYSTEM.—The *blood* presents important changes. The following statements are based on studies made by W. S. Thayer (Studies I and

III): During the first two weeks there may be little or no change in the blood. Profuse sweats or copious diarrhœa may cause the corpuscles—as in the collapse stage of cholera—to rise above normal. In the third week a fall usually takes place in corpuscles and hæmoglobin, and the number may sink rapidly even to 1,300,000 per c. mm., gradually rising to normal during convalescence. When the patient first gets up, there may be a slight fall in the corpuscles. The average maximum loss is about 1,000,000 to the c. mm.

The amount of hæmoglobin is always reduced, usually in a greater relative proportion than the red corpuscles, and during recovery the normal color standard is reached at a later period. Leucopenia is present throughout and baths increase temporarily the number of leucocytes in the peripheral circulation. The absence of leucocytosis is of value in distinguishing typhoid fever from septic fevers and acute inflammatory processes. The large mononuclears are relatively increased. When an acute inflammatory process occurs in typhoid fever the leucocytes show an increase in the polynuclear forms, and this may be of great diagnostic moment.

The post-typhoid anæmia may reach an extreme grade. In one of our patients the blood corpuscles fell to 1,300,000 per c. mm. and the hæmoglobin to about 20 per cent., but these severe grades of anæmia are not common. In the Munich statistics there were 54 cases with extreme anæmia.

The pulse presents no special characters. It is increased in rapidity, but not in proportion to the fever, and this is a special feature in the early stages. There is no acute disease with which, in the early stage, a dicrotic pulse is so frequently associated. Even with high fever the pulse may not be greatly accelerated. As the disease progresses the pulse becomes more rapid, feebler, and small. In 15 per cent. of our cases the rate rose above 140. In the extreme prostration of severe cases it may reach 150 or more, and is a mere undulation—the so-called running pulse. The lowered arterial pressure is manifest in the dusky lividity of the skin and coldness of the hands and feet.

During convalescence the pulse gradually returns to normal, and occasionally becomes very slow. After no other acute fever do we so frequently meet with bradycardia. The pulse may be as low as 30, and instances are on record of still fewer beats to the minute. Some of these are due to temporary heart-block. Tachycardia, while less common, may be a very troublesome and persistent feature of convalescence.

Blood Pressure.—There is a gradual fall during the course to about 100-110 mm. Hg at the beginning of apyrexia. In two or three weeks later the pressure has usually returned to normal. Hæmorrhage usually produces a marked fall both in the systolic and diastolic pressure. In some cases of perforation there may be a sharp rise in systolic pressure. Baths and ice sponges usually cause a rise of 10-20 mm. Hg.

The heart-sounds may be normal throughout. In severe cases, the first sound becomes feeble and there is often heard, at the apex and along the left sternal margin, a soft systolic murmur, which was present in 22 per cent. of our cases. Absence of the first sound is rare. Gallop rhythm is not uncommon. In the extreme feebleness of the graver forms, the first and second sounds become similar, and the long pause is shortened (embryocardia).

Pericarditis is rare and has been met with chiefly in children and with

pneumonia. It was present in 3 of our series and occurred in only 14 of the 2,000 Munich post mortems. *Endocarditis* was found post mortem in 3 cases, and the physical signs suggested its presence in 3 other cases in the series. *Myocarditis* is more common, and is indicated by a progressive weakening of the heart-sounds and enfeeblement of the action of the organ.

Complications in the Arteries.—*Arteritis* with thrombus formation occurred in four cases in the series, one in the branches of the middle cerebral, two in the femoral, and one in the brachial. In one case gangrene of the leg followed. In another case, obliteration of the left femoral artery occurred on the sixteenth day, and of the right femoral on the twentieth day, with gangrene of both feet. Pain, tenderness and swelling occur over the artery, with diminution or disappearance of the pulsations and coldness and blueness of the extremity. In two of the cases these symptoms gradually disappeared, and the pulsation returned not only in the peripheral, but in the affected vessels (Thayer). Keen refers to 46 cases of arterial gangrene, of which 8 were bilateral, 19 on the right side, and 19 on the left.

Thrombi in the Veins.—In our series there were 43 instances, distributed in the following veins: femoral 23, popliteal 5, iliac 5, veins of the calf 5, internal saphenous 3, pulmonary artery and common iliac 1, axillary vein 1 (Thayer). Femoral thrombosis is the most common, and almost invariably in the left vessel, due probably to the fact that the left iliac vein is crossed by the right iliac artery, and the blood flow is not so free. The symptoms are very definite—the fever may increase or recur. Chills occurred in 11 of the cases. Pain and swelling at the site are constantly present, and the thrombotic mass can be felt, not always at first, nor is it well to feel for it. Swelling of the leg follows as a rule, but it is rarely so extreme, and not so painful as in the puerperal cases. In iliac thrombosis the pain may be severe and lead to the suspicion of perforation. Leucocytosis is usually present; in 12 cases it was above 10,000. Five of the 43 patients died, 2 only as a result of the thrombus; in the case of axillary thrombosis from pulmonary embolism, in one from embolism of the inferior cava and right auricle from the dislocation of a piece of thrombus from the left iliac vein. Thayer examined 16 of the patients at varying periods after convalescence, and found in every case more or less disability from the varices and persistent swelling. In some cases, however, the recovery is complete. Conner has emphasized the frequency of thrombosis in the small veins of the legs and feet and suggests that pulmonary embolism of slight extent is a common result.

DIGESTIVE SYSTEM.—Loss of appetite is early, and, as a rule, the relish for food is not regained until convalescence. The tongue presents the changes inevitable in a prolonged fever. Early in the disease it is moist, swollen, and coated with a thin white fur, which, as the fever progresses, becomes denser. It may remain moist throughout. In severe cases, particularly those with delirium, the tongue becomes very dry, partly owing to the fact that such patients breathe with the mouth open. It may be covered with a brown or brownish-black fur, or with crusts between which are cracks and fissures. In these cases the teeth and lips may be covered with a dark brownish matter called *sordes*—a mixture of food, epithelial *débris*, and micro-organisms. By keeping the mouth and tongue clean from the outset, the fissures may be prevented. Acute *glossitis* occurred in one case at the onset of the relapse.

During convalescence the tongue gradually becomes clean, and the fur is thrown off, almost imperceptibly or occasionally in flakes.

The secretion of saliva is often diminished; salivation is rare.

Parotitis was present in 45 of the 2,000 Munich cases. It occurred in 14 cases in our series; of these, 5 died. It is most frequent in the third week in very severe cases. Extensive sloughing may follow in the tissues of the neck. Usually unilateral, and in some cases going on to suppuration, it is regarded as a very fatal complication, but recovery followed in nine of our cases. It may arise from extension of inflammation along Steno's duct. This is probably not so serious a form as when it is hæmatogenous in origin. In four cases the submaxillary glands were involved alone, in one a cellulitis of the neck extended from the gland and proved fatal. Parotitis may occur after the fever has subsided. A remarkable localized sweating in the parotid region is an occasional sequel.

The pharynx may be the seat of catarrh or ulceration. Sometimes the fauces are deeply congested. Membranous pharyngitis, a serious and fatal complication, may come on in the third week. Difficulty in swallowing may result from ulcers of the œsophagus, and in one of our cases stricture followed. The thyroid gland is often enlarged in the acute stages. Thyroiditis may occur with abscess formation years after the attack of typhoid fever. Typhoid bacilli have been found in the pus.

The gastric symptoms are extremely variable. Nausea and vomiting are not common but there are instances in which vomiting, resisting all measures, is a marked feature from the outset, and may cause death from exhaustion. Vomiting does not often occur in the second and third weeks, unless associated with some serious complication. Ulcers have been found in the stomach. Hæmatemesis occurred in 4 of our cases.

Intestinal Symptoms.—Diarrhœa is a very variable symptom, occurring in from 20 to 30 per cent. of the cases. Of 1,500 cases, 516 had diarrhœa before entering and 260 during their stay in hospital. It frequently follows the giving of purgatives and the small percentage in the hospital may be due to the fact that we used no purges or intestinal antiseptics. Its absence must not be taken as an indication that the intestinal lesions are of slight extent. The most extensive ulceration of the small intestine may be seen with the colon filled with solid fæces. The diarrhœa is caused less by the ulcers than by the associated catarrh, and, as in tuberculosis, it is probable that when this is in the large intestine the discharges are more frequent. It is most common toward the end of the first and throughout the second week, but it may not occur until the third or even the fourth week. The number of discharges ranges from 3 to 8 or 10 in the twenty-four hours. They are usually abundant, thin, grayish-yellow, granular, of the consistency and appearance of pea-soup, and resemble, as Addison remarked, the normal contents of the small bowel. Blood may be in small amount and only recognized by the microscope. Sloughs of the Peyer's glands occur as grayish-yellow fragments or occasionally as ovoid masses, an inch or more in length, in which portions of bowel tissue may be found. The bacilli are not found in the stools until the end of the first or the middle of the second week. Constipation was present throughout in 52 per cent. of this series.

Hæmorrhage from the bowels occurs in about 7 per cent. of all cases.

It had occurred in 99 of the 2,000 fatal Munich cases. In 1,500 cases of our series hæmorrhage occurred in 118, and in 12 death followed the hæmorrhage. It occurred in 1,641 (7 per cent.) of 23,721 collected cases. There may be only a slight trace of blood in the stools, but often it is a profuse, free hæmorrhage. It occurs most commonly between the end of the second and

CHART II.—HÆMORRHAGE FROM THE BOWELS. RAPID FALL OF TEMPERATURE.

the beginning of the fourth week, the time of the separation of the sloughs. Occasionally, early in the course, it results simply from the intense hyperæmia. It usually comes on without warning. A sensation of sinking or collapse may be experienced by the patient, the temperature falls, and may drop 6° or 7° in a few hours. Fatal collapse may supervene before the blood

appears in the stool. Occult blood can be found in the stools of many patients without gross hæmorrhage.

It must not be forgotten that melæna may also be part of a general hæmorrhagic tendency (to be referred to later), in which case it is associated with petechiæ and hæmaturia.

Meteorism, a frequent occurrence, is not serious if of moderate grade, but when excessive is usually of ill omen. Owing to defective tone in the walls, in severe cases to their infiltration with serum, gas accumulates in the stomach, small and large bowel, particularly in the last. Pushing up the diaphragm, it interferes with the action of the heart and lungs, and may also favor perforation. Gurgling in the right iliac fossa exists in a large proportion of cases, and indicates simply the presence of gas and fluid fæces in the colon and cæcum.

Abdominal pain and tenderness were present in three-fifths of a series of 500 cases studied with special reference to the point. In some it was only present at the onset. Pain occurred during the course in about one-third of the cases. This is due in some instances to conditions apart from the bowel lesions, such as pleurisy, distention of the bladder, and phlebitis. It may be associated with diarrhœa, severe constipation, perisplenitis, or acute abdominal complications. Pain occurs with some cases of hæmorrhage, but is most constantly present with perforation. In a large group no cause could be found for the pain, and if other symptoms be associated the condition may lead to error in diagnosis. Operation for appendicitis has been performed in the early stage of typhoid fever, owing to the combination of pain in the right iliac fossa, fever and constipation.

PERFORATION.—From one-fourth to one-third of the deaths are due to perforation. Among 34,916 collected cases perforation occurred in 3.1 per cent. While it may occur as early as the first week, in the great majority it is at the height of the disease in the third week, and much more frequently in the severe cases, particularly those associated with tympanites, diarrhœa, and hæmorrhage. It may occur, however, in very mild attacks and with great suddenness, when the patient is apparently progressing favorably.

Symptoms of Perforation.—By far the most important single indication is a sudden, sharp pain of increasing severity, often paroxysmal in character. It is rarely absent, except in the small group of cases with profound toxæmia. The situation is most frequent in the hypogastric region and to the right of the middle line. Tenderness on pressure is present in the great majority of cases, usually in the hypogastric and right iliac regions, sometimes diffuse; it may only be brought out on deep pressure. As LeConte points out, when the perforation happens to be in contact with the parietal peritoneum the local features on palpation are much more marked than when the perforated ulcer is next to a coil or to the mesentery. There may be early irritability of the bladder, with frequent micturition, and pain extending toward the penis. A third important sign is muscle rigidity, increased tension, and spasm on any attempt to palpate. The temperature may rise for a few hours to fall later or may drop at once. The pulse and respiration rate are usually increased. Following these features in a few hours there is usually a reaction, and then the evidences of general peritonitis become manifest to a more or less marked degree. Among the general features, the facies shows changes; there

is increased pallor, a pinched expression, and as the symptoms progress and toward the end a marked Hippocratic facies, a dusky suffusion, and the forehead bathed in a clammy perspiration. The temperature rises with the increase of the peritonitis. The pulse quickens, is running and thready, the heart's action becomes more feeble, and there is an increase in the respiration rate. Vomiting is a variable feature; it is present in a majority of the cases. Hiccough is common and may occur early, but more frequently late.

The local abdominal features are often more important than the general, as it is surprising to notice how excellent the condition of a patient may be with perforative peritonitis. Limitation of the respiratory movements is usually present, perhaps confined to the hypogastric area. Increasing distention is the rule, but perforation and peritonitis may occur, it is to be remembered, with an abdomen flat or even scaphoid. Increasing pain on pressure, increasing muscle spasm and tension of the wall are important signs. Percussion may reveal a flat note in the flanks, due to exudate. A friction may be present within a few hours of the onset of the perforation. Obliteration of the liver flatness in the nipple line may be caused by excessive tympany, but rapid obliteration of liver flatness in a flat, or a not much distended abdomen, is a valuable sign. Examination of the rectum may show fullness or tenderness in the pelvis. Advance in the abdominal signs is an important point.

In some cases there is a rise in the leucocytes, which is a valuable help, but is not constant. Increase in the blood pressure is not constant.

General peritonitis, without perforation of the bowel, may occur by extension from an ulcer, by rupture of a softened mesenteric gland, or, as in one case in our series, from inflammation of the Fallopian tubes. It was present in 2.2 per cent. of the Munich autopsies.

Perforation is almost invariably fatal without operation. In a few cases healing takes place spontaneously or the orifice may be closed by a tag of omentum. There is a group of cases in which hæmorrhage complicates the perforation and adds to the difficulty in diagnosis. In 7 of our 43 cases hæmorrhage accompanied the perforation; in 3 others the hæmorrhage had occurred some days before.

The diagnosis of perforation, easy enough at times, is not without serious difficulties. The conditions for which it was mistaken in our series were: appendicitis, occurring during the course of the typhoid fever, phlebitis of the iliac vein with great pain, hæmorrhage, and in one case a local peritonitis without perforation, for which no cause was found. Recovery followed the exploratory operation in all but one (hæmorrhage case) of the cases. Exploration is justifiable and better than delay in suspicious cases.

ASCITES occurs in rare instances (McPhedran).

The SPLEEN is usually enlarged, and the edge was felt below the costal margin in 71.6 per cent. of our cases. Percussion is uncertain, as, owing to distention of the stomach and colon, even the normal area of dulness may not be obtainable. Enlargement is often not marked in elderly patients. Rupture of the spleen occurs occasionally. Perisplenitis occurs not infrequently.

LIVER.—Symptoms on the part of this organ are rare.

(a) Jaundice of marked grade was present in only 8 cases of our series,

but slight icterus is not uncommon. Catarrh of the ducts, toxæmia, abscess, and occasionally gall-stones are the usual causes.

(b) *Abscess*.—Solitary abscess is exceedingly rare and occurred in but 3 cases in our series. It may occur early in the disease, but most frequently is a sequel. Eberts collected 30 cases, in 9 of which the typhoid bacillus was isolated from the pus. In about half the cases the right lobe was affected. Eighteen of the patients recovered. Abscess may follow the intestinal lesion or a complication as parotitis. Suppurative pylophlebitis may follow perforation of the appendix. Suppurative cholangitis has been described.

(c) *Cholecystitis* occurred in 19 cases of the series. Pain in the region of the gall-bladder is the most constant symptom. Tenderness, muscle spasm with rigidity, and a gall-bladder tumor are present in a majority of the cases. Jaundice is inconstant. Leucocytosis usually occurs. With perforation there may be a marked drop in the fever and the onset of signs of peritonitis. In simple cholecystitis the urgency of the symptoms may abate, and recovery follow. Suppuration may occur with infection of the bile passages. Months or years later the bacilli may cause cholecystitis or gall-stones. Typhoid bacilli have been found in the gall-bladder of patients without any history of typhoid fever.

(d) *Gall-stones*.—Bernheim called attention to the frequency of cholelithiasis after typhoid fever. It is probably associated with the presence of typhoid bacilli in the gall-bladder (see under Gall-Stones).

PANCREAS.—Hæmorrhagic pancreatitis has occurred rarely.

RESPIRATORY SYSTEM.—*Epistaxis* occurs in the early stages of typhoid fever more often than in any other febrile affection. It is occasionally profuse and serious and may occur during the course.

Laryngitis is not very common and œdema, apart from ulceration, is rare. In the United States the laryngeal complications of typhoid fever seem much less frequent than on the Continent. We have twice seen severe perichondritis; both of the patients recovered, one after the expectoration of large portions of the thyroid cartilage. Keen and Lüning collected 221 cases of serious surgical complications of the larynx. General emphysema may follow the perforation of an ulcer. Stenosis is a serious sequence. Paralysis of the laryngeal muscles is not uncommon. Przedborski examined the larynx in 100 consecutive cases and found 25 with paralysis. This is nearly always due to neuritis, sometimes in connection with affections of other nerves.

Bronchitis is one of the most frequent initial symptoms. The sputum is usually scanty. The smaller tubes may be involved, producing urgent cough and even slight cyanosis. Collapse and broncho-pneumonia may also occur.

Lobar pneumonia is met with under two conditions:

(a) At the outset (*pneumo-typhus*) as occurred in three of our cases. After an indisposition of a day or so, the patient is seized with a chill, has high fever, pain in the side, with signs of consolidation and the evidences of an ordinary lobar pneumonia. The intestinal symptoms may not occur until toward the end of the first week or later; the pulmonary symptoms persist, crisis does not occur; the aspect of the patient changes, and by the end of the second week the picture is that of typhoid fever. Spots may then be present and doubts as to the nature of the case are solved. In other instances, in the absence of a characteristic eruption, the case remains doubt-

ful, and it is impossible to say whether the disease has been pneumonia, in which the so-called typhoid symptoms have developed, or whether it was typhoid fever with early implication of the lungs. This condition may depend upon an early localization of the typhoid bacillus in the lung.

(b) Lobar pneumonia forms a serious complication of the second or third week—in 19 of our cases. It was present in over 8 per cent. of the Munich cases. The symptoms are usually not marked. There may be no rusty sputum, and, unless sought for, the condition is frequently overlooked. The etiological agent may vary. Typhoid bacilli have been isolated from the sputum and from the consolidated lungs at autopsy, but in such cases pneumococci may have been originally present, and the typhoid bacilli secondary invaders. In all cases of pneumonia during typhoid fever in the Johns Hopkins Hospital and coming to autopsy, the pneumococcus could be demonstrated in the consolidated lung. Infarction, abscess, and gangrene are occasionally pulmonary complications.

Hypostatic congestion of the lungs and œdema, due to enfeebled circulation, occur in the later periods. The physical signs are defective resonance at the bases, feeble breath sounds, and moist râles on deep inspiration. Dulness at the right base is not uncommon even early in the attack.

Hæmoptysis may occur and cause death. This has resulted from hæmorrhage from an eroded vessel in the edge of a laryngeal ulcer.

Pleurisy was present in about 8 per cent. of the Munich autopsies. It occurred in 2 per cent. of our series. It may occur at the outset—pleuro-typhoid—or during convalescence, in which case it is almost always purulent and due to the typhoid bacillus.

Pneumothorax is rare. Hale White reported two cases, in both of which pleurisy existed. After death, no lesions of the lungs or bronchi were discovered. The condition may be due to straining, or to the rupture of a small abscess. It may occur also during convalescence.

NERVOUS SYSTEM.—Cerebro-spinal Form.—The disease may set in with intense and persistent headache, or a severe neuralgia. Kernig's sign is often present without any evidence of meningeal infection. There are cases in which the effect of the disease is manifested on the nervous system early and with the greatest intensity. There are headache, photophobia, retraction of the neck, marked twitchings of the muscles, rigidity, and even convulsions. In such cases the diagnosis of meningitis is invariably made. The cases showing marked meningeal features during the course may be divided into three groups. First, those with symptoms suggestive of meningitis, but without localizing features and without the anatomical lesions of meningitis at post mortem (meningism). In every series such examples occur. Secondly, the so-called serous meningitis. There is a localization of typhoid bacilli in the cerebro-spinal fluid and a mild inflammatory reaction, but without suppurative meningitis. Cole in 1904 collected 13 such cases, 5 of them in our series, and Bayne-Jones collected 17 cases from the literature since 1904. Probably more frequent lumbar punctures will show that this occurs not infrequently. Thirdly, true typhoid suppurative meningitis due to *B. typhosus*. Only one such case occurred in our series, and Cole collected 13 from the literature. Bayne-Jones collected 18 additional cases.

Meningitis in typhoid fever is occasionally due to other organisms, as the tubercle bacillus or the meningococcus. Marked convulsive movements, local or general, with coma and delirium, are seen in thrombosis of the cerebral veins and sinuses.

Delirium, usually present in very severe cases, is much less frequent under a rigid plan of hydrotherapy. It may exist from the outset, but usually does not occur until the second or third week. It may be slight and only nocturnal. It is, as a rule, a quiet delirium, though there are cases in which the patient is noisy and constantly tries to get out of bed, and, unless carefully watched, may escape. The patient does not often become maniacal. In heavy drinkers the delirium may have the character of delirium tremens. Even in patients who have no positive delirium, the mental processes are usually dulled and the aspect is listless and apathetic. In severe cases the patient passes into a condition of unconsciousness. The eyes may be open, but he is oblivious to all surrounding circumstances and neither knows nor can indicate his wants. The urine and fæces are passed involuntarily. In this pseudo-wakeful state, or coma vigil, the eyes are open and the patient is constantly muttering. The lips and tongue are tremulous; there are twitchings of the fingers and wrists—subsultus tendinum and carphologia. He picks at the bedclothes or grasps at invisible objects. These are most serious symptoms and always indicate danger.

Convulsions are rare. There were 7 instances in our series, with 3 deaths. They occur: first, at the onset, particularly in children; secondly, as a manifestation of the toxæmia; and thirdly, as a result of severe cerebral complications—thrombosis, meningitis, or acute encephalitis. Occasionally in convalescence convulsions may occur from unknown causes.

Neuritis, which is not uncommon—11 cases in the series—may be multiple or local. Multiple neuritis comes on usually during convalescence. The legs may be affected, or the four extremities. The cases are often difficult to differentiate from those with subacute poliomyelitis. Recovery is the rule.

Local Neuritis.—This may occur during the height of the fever or after convalescence is established. It may set in with agonizing pain, and with sensitiveness of the affected nerve trunks. The local neuritis may affect the nerves of an arm or of a leg, and involve chiefly the extensors, so that there is wrist-drop or foot-drop. The arm or leg may be much swollen and the skin over it erythematous. A curious condition, probably a local neuritis in some but in others due to phlebitis, is that described by Handford as tender toes. The tips and pads of the toes, rarely the pads at their bases, become exquisitely sensitive, so that the patient can not bear the weight of the bedclothes. There is no discoloration or swelling, and the pain disappears usually within a week or ten days.

Poliomyelitis may occur with the symptoms of acute ascending paralysis and prove fatal in a few days. More frequently it is less acute, and causes either a paraplegia or a limited atrophic paralysis of one arm or leg.

Hemiplegia is a rare complication. Smithies (1907) collected 40 cases, in 26 of which aphasia occurred and in 10 the hemiplegia was preceded by convulsions. In 21 cases the paralysis was on the right side. The lesion is usually thrombosis of the arteries, less often a meningo-encephalitis. The

aphasia usually disappears. *Aphasia*, apart from hemiplegia, occurs rarely and usually in children. The prognosis is good.

The superficial abdominal reflexes may disappear early in the course and not return until convalescence, but this is not constant and can not be regarded as important in diagnosis.

True *tetany* occurs sometimes, and has been reported in connection with certain epidemics. It may set in during the height of the disease.

Typhoid Psychoses.—There are three groups of cases: first, an initial delirium, which may be serious, and cause the patient to wander from his home, or he may become maniacal; secondly, the psychosis associated directly with the pyrexia and the toxæmia; in a few cases this outlasts the disappearance of the fever for months or even years; and, lastly, the asthenic psychosis of convalescence, more common after typhoid than after any other fever. The prognosis is usually good. Edsall studied the condition in children, finding 69 cases, of which 43 recovered.

There is a distressing post-typhoid neurasthenia, in which for months or even for years the patient is unable to get into harmony with his surroundings.

SPECIAL SENSES.—*Eye*.—*Conjunctivitis*, simple or phlyctenular, sometimes with keratitis and iritis, may develop. Panophthalmitis has been reported in one case in association with hæmorrhage (Finlay). Loss of accommodation may occur, usually in the asthenia of convalescence. Oculo-motor paralysis has been seen, due probably to neuritis. *Retinal* hæmorrhages may occur alone or in association with other hæmorrhagic features. Double optic neuritis has been described and may be independent of meningitis. Atrophy may follow, but these complications are excessively rare. Cataract may follow inflammation of the uveal tract. Other rare complications are thrombosis of the orbital veins and orbital hæmorrhage. (See de Schweinitz in Keen's monograph for full consideration of the subject.)

Ear.—Deafness is common during the course but usually is not permanent. Otitis media is not infrequent, 2.5 per cent. in Hengst's collected cases. We never found the typhoid bacillus in the discharge. Serious results are rare; only one case of mastoid disease occurred in our series. The otitis may set in with a chill and an aggravation of the fever.

URINARY SYSTEM.—*Retention of urine* is an early symptom and may cause abdominal pain. It may recur throughout the attack. *Suppression of urine* is rare. The urine is usually diminished at first, has the ordinary febrile characters, and the pigments are increased. *Polyuria* is not very uncommon. While most common during convalescence, the increase may be sudden in the second week at the height of the fever. *The amount* of urine depends very much on the fluid taken. Patients who take large quantities of water may pass enormous amounts, 10 or 15 litres. One of our patients passed 33 litres in one day!

Typhoid bacilluria occurs in about one-third of the cases if hexamine is not given. The urine may be turbid from their presence and in the test-tube give a peculiar shimmer. Bacilluria may occur without pyuria or any symptoms of renal or bladder trouble. The bacilli may be present for a few days, intermittently or for weeks to years after the attack (see Gwyn, Studies III).

The renal complications in typhoid fever may be thus grouped:

(a) Febrile albuminuria is common and of no special significance. It was present in 999 of 1,500 cases, 66 per cent. Casts were present in 568 cases, 37.8 per cent. Hæmoglobinuria occurred in one case.

(b) Acute nephritis at the onset or during the height of the disease—the nephro-typhus of the Germans, the fièvre typhoïd à forme rénale of the French—may set in, masking in many instances the true nature of the malady. After an indisposition of a few days there may be fever, pain in the back, and the passage of a small amount of bloody urine.

(c) Nephritis during convalescence is rare, and is usually associated with anæmia and œdema. Chronic nephritis is a most exceptional sequel.

(d) The lymphomatous nephritis produces, as a rule, no symptoms.

(e) Pyuria, a not uncommon complication, may be associated with the typhoid or the colon bacillus, less often with staphylococci. It usually disappears during convalescence. It may be due to a simple catarrh of the bladder, rarely to an intense cystitis, sometimes to pyelitis. Gangrene of the bladder wall may occur, usually after retention. The urine is purulent and bloody, and contains fragments of bladder mucosa.

(f) Post-typhoid Pyelitis.—One or both kidneys may be involved, either at the height of the disease or during convalescence. There may be blood and pus at first, later pus alone, varying in amount. A severe pyelonephritis may follow. The colon bacillus is often the organism present. Perinephric abscess is a rare sequel.

GENERATIVE SYSTEM.—Orchitis is occasionally met with. Kinnicutt collected 53 cases in the literature. It may be associated with a catarrhal urethritis. Induration or atrophy may occur, and more rarely suppuration. It was present in 4 cases of our series. In 1 case double hydrocele developed suddenly on the nineteenth day (Dunlap). Prostatitis occurs rarely.

Acute mastitis, which may go on to suppuration, is a rare occurrence. It was present in 3 cases of our series during the fever and in one late in convalescence.

OSSEOUS SYSTEM.—Among the most troublesome of the sequelæ are the bone lesions which in a few cases occur at the height of the disease or even earlier. Of 237 cases collected by Keen there was periostitis in 110, necrosis in 85, and caries in 13. They are much more frequent than the figures indicate. The lesion may not appear until many years after the attack of typhoid fever. The legs are chiefly involved. In Keen's series the tibia was affected in 91 cases, the ribs in 40. The typhoid bone lesion is apt to form what the old writers called a cold abscess. Only a few of the cases are acute. Chronicity, indolence, and a remarkable tendency to recurrence are perhaps the three most striking features. A bony node may be left by the typhoid periostitis.

Arthritis was present in 8 cases of our series. Keen collected 84 cases from the literature. It may be monarticular or polyarticular. One of the most important points relating to it is the frequency with which spontaneous dislocations occur, particularly of the hip.

Typhoid Spine (Gibney).—During the disease but more often during convalescence, the patient complains of pain in the lumbar and sacral regions, perhaps after a slight jar or shock. Stiffness of the back, pain on movement,

sometimes radiating, and tenderness on pressure are the chief features, but there are in addition marked nervous manifestations. There is rigidity and fixation of the spine, usually in the lower part. Kyphosis occurs in some cases. The X-ray plates may show definite bony change. There is usually spondylitis or perispondylitis. The duration is weeks or months, but the outlook is good.

The *muscles* may be the seat of degeneration but it rarely causes any symptoms. Hæmorrhage occasionally occurs into the muscles, and late in protracted cases abscesses may follow. Rupture of a muscle, usually the rectus abdominis, may occur, possibly associated with acute hæmorrhagic myositis. *Painful muscles* are not uncommon, particularly in the calves (Studies III). Painful cramps may also occur. In some of the cases of painful legs the condition is a myositis; in others the swelling and pain may be due to thrombosis in the deeper veins.

Post-typhoid Septicæmia and Pyæmia.—In very protracted cases after defervescence a slight fever (100° - 101° F.) may recur with sweats, which is possibly septic. In other cases for two or three weeks there are recurring chills, often of great severity. They are usually of no moment in the absence of signs of a complication. (See Studies II and III.)

Typhoid *pyæmia* is not common. (a) Extensive furunculosis may be associated with irregular fever and leucocytosis. (b) Following the fever there may be multiple subcutaneous "cold" abscesses, often with a dark, thin bloody pus. Pratt isolated the bacillus in pure culture from subcutaneous abscesses. (c) A crural thrombus may suppurate and cause a widespread pyæmia. (d) In rare instances suppuration of the mesenteric glands, of a splenic infarct, a sloughing parotid bubo, a perinephric or perirectal abscess, acute necrosis of the bones, or a multiple suppurative arthritis may cause pyæmia. In other cases following bed-sores or a furunculosis a general infection with pyogenic organisms occurs with fatal results. In three such cases in our series staphylococci were cultivated from the blood. In one case with many chills late in the disease, and the general condition excellent, typhoid bacilli were cultivated from the blood. The colon bacillus may also be found in blood cultures.

Association of Other Diseases.—Erysipelas is a rare complication, most common during convalescence. Measles or scarlet fever may develop during the fever or in convalescence. Chicken-pox and noma have been reported in children. Pseudo-membranous inflammations may occur in the pharynx, larynx, or genitals.

Malarial and typhoid fevers may be associated, but a majority of the cases of so-called typho-malarial fever are either remittent malarial fever or true typhoid. It is interesting to note that among 1,500 cases of typhoid fever plasmodia were found in the blood in only 3 cases. (See Lyon, Studies III.) Many of the typhoid fever patients came from malarious regions.

The symptoms of influenza may precede the typhoid fever, or the two diseases may run concurrently. There are cases of chronic influenza which simulate typhoid fever very closely.

Typhoid Fever and Tuberculosis.—(a) The diseases may coexist. A person with chronic tuberculosis may contract the fever. Of 105 autopsies in typhoid fever, 7 presented marked tuberculous lesions. Miliary tuberculosis

and typhoid fever may occur together. (b) Cases of typhoid fever with pulmonary and pleuritic symptoms may suggest tuberculosis at the onset. (c) There are types of tuberculosis infection which may simulate typhoid fever: the acute miliary form; the acute septicæmic form; tuberculous meningitis; tuberculous peritonitis; the acute toxæmia of certain local lesions; and forms of ordinary pulmonary tuberculosis. And, lastly, pulmonary tuberculosis may follow typhoid. In a large majority of such cases from the onset the disease has been tuberculosis, which has begun with a low fever and features suggestive of typhoid fever.

In epilepsy and in chronic chorea the fits and movements usually cease during an attack, and in typhoid fever in a diabetic subject the sugar may be absent during the height of the disease.

Varieties.—Typhoid fever presents an extremely complex symptomatology. Many forms have been described, some of which present exaggeration of common symptoms, others modification in the course, others again greater intensity of action of the poison on certain organs. When the nervous system is specially involved, it has been called the cerebro-spinal form; when the kidneys are early and severely affected, nephro-typhoid; when the disease begins with pulmonary symptoms, pneumo-typhoid; with pleurisy, pleuro-typhoid; when characterized throughout by profuse sweats, the sudoral form of the disease. It is enough to remember that typhoid has no fixed and constant course, that it may set in occasionally with symptoms localized in certain organs, and that many of its features are extremely variable—in one epidemic uniform and text-book-like, in another slight or not met with. This diversified symptomatology has led to many errors, and in the absence of the salutary lessons of morbid anatomy it is not surprising that practitioners are so often led astray. We may recognize the following varieties:

(a) The *mild* and *abortive* forms. Much attention has been paid to the milder varieties—the typhus lævissimus of Griesinger. Woodruff called special attention to the great danger of neglecting these mild forms, which are often spoken of as mountain fever and malarial fever, “acclimation,” “ground,” and “miasmatic” fevers. During an epidemic there may be cases so mild that the patient does not go to bed. The onset may be sudden, particularly in children. The general symptoms are slight, the pulse rate not high, the fever rarely above 102°. Rose spots are usually present, with splenic enlargement. Diarrhœa is rare. The Widal reaction is present in a majority of the patients. There may be a marked tendency to relapse. While infrequent, characteristic complications and sequelæ may give the first positive clue to the nature of the trouble. Briggs studied 44 of these mild cases from our series in which the fever lasted 14 days or less. There were three relapses. It can not be too forcibly impressed upon the profession that it is just by these mild cases, to which so little attention is paid, that the disease may be kept up in a community.

(b) The *grave* form is usually characterized by high fever and pronounced nervous symptoms. In this category come the very severe cases, setting in with pneumonia and nephritis, and with the very intense gastro-intestinal or cerebro-spinal symptoms.

(c) The *ambulatory* form is particularly common in hospital practice. The symptoms are usually slight, and the patient scarcely feels ill enough

to go to bed. He has languor, perhaps slight diarrhoea, but keeps about and may even attend to his work throughout the entire attack. In other instances delirium sets in. The worst cases of this form are seen in sailors, who keep up and about, though feeling ill and feverish. When brought to the hospital they often have symptoms of a most severe type. Hæmorrhage or perforation may be the first marked symptom of this ambulatory type. Sir W. Jenner called attention to the dangers of this form, and particularly to the grave prognosis in those who traveled far with the disease in progress.

(d) *Hæmorrhagic Typhoid Fever*.—This is excessively rare. Among Ouskow's 6,513 cases there were 4 fatal cases with general hæmorrhagic features. Only three instances were present in our series. Hæmorrhages may be marked from the outset, but more commonly they come on during the course. The condition is not necessarily fatal. (See Hamburger, Studies III.)

(e) An afebrile typhoid fever is recognized by some authors, but there is usually slight fever. The patients present lassitude, headache, furred tongue, loss of appetite, slow pulse, and even the spots and enlarged spleen.

TYPHOID FEVER IN CHILDREN.—Griffith collected 325 cases in children under two and a half years; 111 of these were in the first year. Out of 278 cases in which the result was recorded, 142 died. The cases are not very uncommon. The high mortality in Griffith's series was probably due to the fact that only the more serious cases are reported. The abdominal symptoms are usually mild; fatal hæmorrhage and perforation are rare. Among sequelæ, aphasia, noma, and bone lesions are stated to be more common in children than in adults. Two of our cases were under one year of age.

TYPHOID FEVER IN THE AGED.—After the sixtieth year the disease runs a less favorable course, and the mortality is high. The fever is less, but complications are more common, particularly pneumonia and heart-failure.

TYPHOID FEVER IN PREGNANCY.—Pregnancy affords no immunity against typhoid. In 1,500 of our cases, 438 of which were females, there were 6 cases. Goltdammer noted 26 pregnancies in 600 cases of typhoid fever in the female. It is more commonly seen in the first half of pregnancy. The pregnancy is interrupted in about 65 per cent. of the cases, usually in the second week of the disease. There may be puerperal infection with the typhoid bacillus. One such case showed a localized lesion of the chorion, from which bacilli were obtained (Little).

TYPHOID FEVER IN THE FETUS.—The typhoid bacillus may pass through the placenta to the child, causing a typhoid septicæmia, without intestinal lesions. Lynch collected 16 such cases. Infection of the fetus does not necessarily follow, but when infected the child dies, either in utero or shortly after birth. The Widal reaction obtained with fetal blood does not indicate that the child has survived infection, as the agglutinating substances may filter through the placenta. They may also be transmitted to the nursling through the milk, and cause a transient reaction. The reaction could not be obtained with fetal blood from which typhoid bacilli were cultivated (Lynch).

RELAPSE.—Relapses vary in frequency in different epidemics, and, it would appear, in different places. The percentages of different authors range from 3 to 15 or 18 per cent. In 1,500 cases there were 172 relapses, 11.4 per cent. Among 28,057 collected cases 8.8 per cent. had a relapse. We may recognize the ordinary, the intercurrent, and the spurious relapse.

The *ordinary relapse* sets in after complete defervescence. The average duration of the interval of normal temperature is five or six days. In one of our cases there was apyrexia for twenty-three days, followed by a relapse of forty-one days' duration; then apyrexia for forty-two days, followed by a second relapse of two weeks' duration. As a rule, two of the three important features—step-like temperature at onset, roseola, an enlarged spleen—should be present to justify the diagnosis of a relapse. The intestinal symptoms are variable. The onset may be abrupt with a chill, or the temperature may have a typical ascent. The number of relapses ranges from 1 to 6. In a case at the Pennsylvania Hospital in 1904 the disease lasted eleven months and four days, during which there were six relapses. The relapse is usually less severe, of shorter duration and the mortality is low.

The *intercurrent relapse* is common, often severe, and is responsible for many of the most protracted cases. The temperature drops and the patient improves; but after remaining between 100° and 102° for a few days, the fever again rises and the patient enters upon another attack, which may be more protracted, and of much greater intensity than the original one.

Spurious relapses have already been mentioned as post-typhoid elevations of temperature. They are recrudescences of the fever due to a number of causes. It is not always easy to determine whether a relapse is present, particularly in cases in which the fever persists for only five or seven days without rose-spots and without enlargement of the spleen.

Undoubtedly a reinfection from within, yet of the conditions favoring the occurrence of relapse we know little. Durham advanced an interesting theory: Every typhoid infection is a complex phenomenon caused by groups of bacilli alike in species but not identical, as shown by their serum reactions. The antibodies formed in the blood during the primary attack neutralize only one (or several) groups, the remaining groups still preserving their pathogenic power. From some cause these latter groups may multiply sufficiently to cause a reinfection. Multiple relapses may be similarly explained.

Diagnosis.—There are several points to note. In the first place, typhoid fever is one of the common continued fevers. Secondly, it is extraordinarily variable in its manifestations. Thirdly, there is no such hybrid malady as typho-malarial fever. Fourthly, errors in diagnosis are inevitable, even under the most favorable conditions.

(a) *General*.—No single symptom or feature is characteristic. The onset is often suggestive, particularly the occurrence of epistaxis, and (if seen from the start) the ascending fever. The steadiness of the fever for a week or longer after reaching the fastigium is an important point. The irregular remittent character in the third week, and the intermittent features with chills, are common sources of errors. While there is nothing characteristic in the pulse, dicrotism is so much more common early in typhoid fever that its presence is always suggestive. The rash is the most valuable single sign, and with the fever usually clinches the diagnosis. The enlarged spleen is of less importance, since it occurs in many febrile conditions, but with the fever and the rash it completes a diagnostic triad. The absence of leucocytosis is a valuable sign. Typhoid should be suspected in every doubtful fever.

(b) *Specific*.—(1) *Typhoid Bacilli from the Blood*.—This is especially useful early in the disease, in doubtful cases and in the acute septic forms.

(2) *Typhoid Bacilli from the Duodenum*.—Cultures from the duodenum obtained through the duodenal tube are often positive.

(3) *Typhoid Bacilli from the Stools*.—Cultures from the stools are of diagnostic value at all stages.

(4) *Typhoid Bacilli from the Urine*.—In some cases positive cultures may be obtained before the Widal test is positive. Routine cultures are frequently of diagnostic value.

(5) *The Agglutination Test*.—In 1894 Pfeiffer showed that cholera spirilla, when introduced into the peritoneum of an immunized animal, or when mixed with the serum of immunized animals, lose their motion and break up. This "Pfeiffer's phenomenon" was thoroughly studied by Durham and the specificity of the reaction demonstrated. A. S. Grünbaum and Widal made the method available in clinical work.

Macroscopic Method.—This may be done with living or dead organisms and has the advantage of use away from a laboratory. The diluted serum and organisms are mixed in a tube of small calibre (dilution 1 to 50 or 1 to 100). With a positive reaction there should be complete precipitation leaving a clear fluid above in twenty-four hours.

Microscopic Method.—If the reaction is positive the bacilli lose their motility and collect in clumps. With Dreyer's method of standard cultures of constant and known sensitiveness it is possible to follow the serum changes in typhoid or paratyphoid infection. Whatever be the infection the agglutination for that bacillus will show (a) a marked rise in an early stage and (b) a marked fall later in the infection. If the patient's serum already contains agglutinins for one or more of the bacilli (owing to inoculation), the following phenomena will be noted (a) there is no change in the inoculation agglutinins or (b) a slight rise occurs, followed by a slight fall—an alteration which may be caused by a number of non-specific stimuli. A well marked rise or fall of the titre is the only positive evidence of active infection that can be obtained with the agglutination test and is probably the best evidence afforded by any test except a successful blood culture.

The serum reaction is of great value and with the newer methods the reactions are of equal importance in inoculated and uninoculated persons and in the paratyphoids.

(6) *Ophthalmic-Reaction*.—A solution of one-third to one-half of a milligram of "typho-protein" derived from many different strains of typhoid bacilli is instilled into the conjunctival sac. A typical reaction is marked by deep congestion of the conjunctiva of the lower lid and the caruncle. It reaches its maximum in six hours. A positive reaction is obtained most often during the febrile period, frequently before the agglutination reaction is given. The simplicity of the method and the absence of discomfort are valuable features. A cutaneous method has also been employed.

(7) *Autolysate-Precipitin Reaction*.—This does not depend upon any immune reaction in the patient but upon the presence of the chemical constituents of the typhoid bacillus in the excretions. It signifies the presence of living typhoid bacilli in the patient. It may be useful in the diagnosis of atypical cases and should eliminate the difficulty due to previous anti-typhoid inoculation. It can be used either with the urine or stools (Laird, Conover and Butts).

(c) *Atropine Test (Marris)*.—The patient should remain as quiet as possible during the test, which should not be done until at least an hour after the last feeding. The pulse rate is counted until it is found to be steady. Atropine gr. 1/33 (0.002 gm.) is given hypodermically, and 25 minutes later the pulse is counted each minute until any rise which follows the injection has begun to pass off. The difference between the average pulse rate before the injection and the maximum after it gives the acceleration due to the atropine. The highest average count is usually about thirty minutes after the injection. If the “escape” is 14 or less, the diagnosis is probably typhoid or para-typhoid fever; if 15 or more the reaction is negative. Three negative reactions within the first fortnight of a febrile illness exclude the typhoid group. A negative reaction after the end of the second week or when the fever has fallen may be unreliable. This test is most useful from the fifth to the fourteenth day, but a series of negative reactions later than the fourteenth day may be generally taken as evidence against typhoid infection. A positive reaction may be obtained in those over fifty years of age, especially if arteriosclerotic. In patients with a pulse rate of 100 or over, a positive reaction has to be taken with caution; a negative reaction in patients who are very toxic is not conclusive.

COMMON SOURCES OF ERROR IN DIAGNOSIS.—An early and intense localization of the infection in certain organs may give rise to doubt at first.

Patients with severe headache, photophobia, delirium, twitching of the muscles and retraction of the head are often regarded as having cerebro-spinal meningitis. Under such circumstances it may for a few days be impossible to make a satisfactory diagnosis. Until the appearance of abdominal symptoms or the rash, it may not be quite possible to determine the nature of the case. The lumbar puncture is a great help.

The misleading pulmonary symptoms, which occasionally occur at the onset, have been mentioned. The bronchitis rarely causes error, though it may be intense and attract the chief attention. More difficult are the cases setting in with chill and followed rapidly by pneumonia. Such a case may be shown to a class one week as typical pneumonia, and a fortnight later as typhoid fever. There is less danger of mistaking the pneumonia which occurs at the height of the disease. Early involvement of the pleura or the kidneys may for a time obscure the diagnosis.

Of diseases with which typhoid fever may be confounded, malaria, certain forms of pyæmia, acute tuberculosis, tuberculous peritonitis, *Bacillus fecalis alkaligenes* infection, undulant fever, trichiniasis and typhus fever are the most important.

Bacillus fecalis alkaligenes infection usually has an abrupt onset and shows symptoms much like typhoid fever. The initial fever lasts for two to five days and then is normal for a few days. There may be several recrudescences. Toxæmia may be marked. Blood cultures and agglutination tests are essential in diagnosis. Recovery is the rule. The treatment is symptomatic.

From malarial fever, typhoid is, as a rule, readily recognized. There is no such disease as typho-malarial fever. Typhoid fever and malarial fever may coexist in the same patient but this is rare. The term typho-malarial fever should be abandoned. The autumnal type of malarial fever may present a striking similarity to typhoid fever and differentiation may be made only by the blood examination. There may be no chills, the remissions may be

extremely slight, there is a history perhaps of *malaise*, weakness, diarrhoea, and sometimes vomiting. The tongue is furred and white, the cheeks flushed, the spleen slightly enlarged, and the temperature continuous, or with slight remissions. The æstivo-autumnal malarial parasite may be difficult to find.

Pyæmia.—The long-continued fever of obscure, deep-seated suppuration, without chills or sweats, may simulate typhoid. The more chronic cases of ulcerative endocarditis may be diagnosed typhoid fever. The presence or absence of leucocytosis is an important aid. The Widal reaction and the blood cultures offer valuable help.

Acute miliary tuberculosis is not infrequently mistaken for typhoid fever. The points in differential diagnosis will be discussed under that disease. *Tuberculous peritonitis* in certain of its forms may closely simulate typhoid fever, and will be referred to in another section.

Undulant fever may be a source of difficulty. The absence of the positive findings in typhoid infection and the macroscopic agglutination test and positive blood cultures for *Brucella abortus* are distinctive.

Trichiniasis resembles typhoid fever, but the œdema, local muscular tenderness, leucocytosis and eosinophilia should make the diagnosis clear.

The early abdominal pain, etc., may lead to the diagnosis of appendicitis.

The mild endemic form of *typhus fever* described by Brill may be regarded as typhoid fever, but the character of the rash, the absence of the agglutination reaction, negative results of blood cultures and the course are against this. The majority of cases are probably diagnosed as typhoid fever.

Prognosis.—(a) **DEATH-RATE.**—The mortality is very variable, ranging in private practice from 5 to 12 and in hospital practice from 7 to 20 per cent. In some large epidemics the death-rate has been very low. In recent years the mortality from typhoid fever has diminished, and hydrotherapy has reduced the death-rate in a remarkable manner, even as low as 5 or 6 per cent. Of the 1,500 cases in our series, 9.1 per cent. died.

(b) **SPECIAL FEATURES.**—Unfavorable symptoms are high fever, toxic symptoms with delirium, meteorism, and hæmorrhage. Perforation renders the outlook hopeless unless operation is done early. Fat subjects stand typhoid fever badly. The mortality in women is greater than in men. The complications and dangers are more serious in the ambulatory form in which the patient has kept about for a week or ten days. Early involvement of the nervous system is a bad indication; and the low, muttering delirium with tremor means a close fight for life. Prognostic signs from the fever alone are deceptive. A temperature above 104° may be well borne if the nervous system is not involved. The degree of bacteræmia is of value; the greater this is the worse the prognosis.

(c) **SUDDEN DEATH.**—It is difficult in many cases to explain this most lamentable of accidents. There are cases in which neither cerebral, renal, nor cardiac changes have been found. Fibrillation of the ventricle may be the cause in some cases. Sudden death occurs more frequently in men than in women, according to Dewèvre's statistics, in a proportion of 114 to 26. It may occur at the height of the fever, and also during convalescence.

Prophylaxis.—In cities the prevalence of typhoid fever is directly proportionate to the character of the drainage and the purity of the water-supply. With their improvement the incidence is reduced materially. In general

the disease exists to a proportionately greater extent in the country than in the city. The water-supply of the latter is usually better than in the country, where the privy vault is often in close proximity to the well. Chlorination of water-supplies has been very largely responsible for the great decrease in typhoid fever in cities.

But it is not only through water that the disease is transmitted. The bacilli may be carried by milk, oysters, uncooked vegetables, etc. Flies play an important part in the spread of the disease. Many cases undoubtedly arise by direct infection. But through whatever channel the infection occurs, for new cases to arise the bacilli must be obtained from another patient. Under ordinary circumstances the bacilli do not live and thrive long outside the body. To stamp out typhoid fever requires (1) the recognition of all cases, including the typhoid carriers and (2) the destruction of all typhoid bacilli as they leave the patient. It is as much a part of the physician's duty to look after these points as to take care of the patient. Mild cases of fever are to be regarded with suspicion.

From the standpoint of prophylaxis, the question practically narrows down, to disinfection of the urine, stools, sputum (in the few cases where bacilli are present), and of objects which may be contaminated accidentally by these excretions. The nurse or attendant should be taught to regard every specimen of urine as a pure culture of typhoid bacilli, and to exercise the greatest care in preventing the scattering of drops of urine over the patient, bedding or floor, or over the hands of the attendant.

To disinfect the urine the best solutions are carbolic acid, 1-20, in an amount equal to that of the urine, or bichloride of mercury, 1-1,000, in an amount one-fifth that of the fluid to be sterilized. These mixtures with the urine should stand at least two hours. Hexamine causes disappearance of the bacilli from the urine when bacilluria is present, but under no circumstances should its administration permit the disinfection of the urine to be neglected. For the stools, heat is the most efficient and can be employed in hospitals by special hoppers in which steam is used. Of solutions, carbolic acid or freshly prepared milk of lime is most useful. The stool should be mixed with at least thrice its volume of these solutions and allowed to stand for several hours. For the disinfection of the bath water chloride of lime is the best and even when the water contains coarse faecal matter, 250 gm. (one-half pound) of chloride of lime will render the ordinary bath of 200 litres sterile in one-half hour.

If there be any expectoration, the sputum should receive the same care as in tuberculosis. It is best to collect it in small cloths, which may be burned.

All the linen from the patient's bed or person should be soaked for two hours in 1-2,000 bichloride solution, and then boiled in the laundry. All dishes should be boiled before leaving the patient's room.

The nurse should ~~wear~~ a rubber apron when giving tubs or working over a typhoid patient, and this should be washed frequently with bichloride of mercury solution. The nurse should wear rubber gloves when giving tubs and soak her hands thoroughly in 1-1,000 bichloride solution.

It is impossible to deal with all the possible modes of spread of the infection. Keeping in mind that everything leaving the patient should be steri-

lized, a person of ordinary intelligence can carry out very satisfactory prophylaxis. Those nursing the patient should not handle food for others.

Should the typhoid fever patient be isolated? To prevent direct infection of others a moderate degree of isolation should be carried out, though this need not be absolute as in the exanthemata. The windows should have fly screens in summer. After recovery the room should be disinfected.

An important question is as to the necessity for the isolation of typhoid patients in special wards in hospitals. At present this is not generally done in the United States. When, however, in a hospital with as good sanitary arrangements as the Johns Hopkins possesses, and in which all possible precautions are taken to prevent infection from patient to patient, 1.8 per cent. of a series were of hospital origin, the advisability of isolation of typhoid fever patients is certainly worth considering. On the other hand, in the general hospital, with students in the wards, the cases are more thoroughly studied, and in graver complications, as perforation, it is of the greatest advantage to have the early co-operation of the house surgeon.

When the disease is prevalent the drinking water and the milk should be boiled. Travellers should drink mineral water rather than ordinary water or milk. Care should be taken to thoroughly cook oysters which have been fattened or freshened in streams contaminated with sewage. While in camps it is easy to boil and filter the water, with troops on the march it is a very different matter. Various chemical methods have been recommended of which *chlorination* has proved the most satisfactory.

During an epidemic the early recognition of all cases followed by isolation and thorough disinfection is most important. *Preventive inoculation* should be given as generally as possible. Every effort should be made to find the source of infection with a thorough search for *carriers*, especially in local outbreaks. In the search for *carriers* the agglutination test is not sufficient and cultural studies of the contents of the duodenum, of the *feces* and urine should be made.

PREVENTIVE INOCULATION.—Introduced by Wright this has proved of inestimable value in reducing the occurrence of typhoid fever. The experience of the European War gave ample proof of this. The material used is a bouillon or agar culture of bacilli heated to a temperature of 53° to 55° C. in order to kill them. Lysol or tricresol may be added. Three inoculations are given at intervals of ten days. The use of a sensitized vaccine has some advantages.

A triple vaccine against typhoid and paratyphoid A and B should be used. Untoward results are rare. The inoculation fever begins in from four to six hours and may reach 101° or even 103° to 104°. Headache, chilliness, pains in the back and limbs, and vomiting may occur. In many there is only a transient indisposition. More severe symptoms may occur, such as arthritis, fugitive erythema, diarrhoea, abdominal pains, septicæmia, with pneumonia, pleurisy and pericarditis. In a few cases a fever resembling typhoid has followed. No case of a fatality due directly to the inoculation was found. A light diet, avoidance of stimulants and rest lessen the possibility of serious sequels. The evidence so far points to a persistence of the protective effect for some years after inoculation. The typhoidin skin reaction is a guide to

the duration of immunity. If infection results after proper inoculation it is probably due to a very large dose of typhoid bacilli. The oral administration of typhoid vaccine is advised by some and there is considerable evidence of its value. The hypodermic method is probably more reliable.

Treatment.—(a) GENERAL MANAGEMENT.—The profession was long in learning that typhoid fever is not a disease to be treated mainly with drugs. Careful nursing, a proper diet, and hydrotherapy are the essentials in a majority of cases. The patient should be in a well-ventilated room, strictly confined to bed from the outset, and there remain until convalescence is well established. The bed should be single, not too high, and the mattress should not be too hard. The woven wire bed, with soft hair mattress, upon which are two folds of blanket, combines the two great qualities of a sick-bed, smoothness and elasticity. A rubber cloth should be placed under the sheet. An intelligent nurse should be in charge. When this is impossible, the physician should write out specific instructions regarding diet and treatment of the discharges and bed-linen. The common initial purge is better omitted.

(b) DIET.—More liberality is now generally practised, as was advised years ago by Austin Flint and strongly supported by Shattuck, Kinnicutt and others. The patient should be nourished as well as possible and food given with a value of 2,500 to 3,000 calories and containing about 70 grams of protein if conditions permit. The bulk of the food should be liquid and milk or its modifications form the largest part. Milk in any form, cream, ice cream, cocoa, tea or coffee with cream, strained soups, eggs, either the white or the whole egg, raw or soft boiled, gruels and jellies may be given. The milk may be boiled or diluted, or some modification given—peptonized milk, fermented milk, malted milk, buttermilk or whey. Soft food is often permissible, such as milk toast, custard, junket, crackers and milk, bread and butter, and mashed potatoes. It is important to give carbohydrate freely to spare the body proteins, and this is aided by the addition of milk sugar to the diet, given with each feeding of milk. Cane sugar or dextrose can be given freely. The food should be chosen for each patient and a routine diet not followed. In case of digestive disturbance—undigested food in the stools, diarrhoea, meteorism—the diet should be made very simple, buttermilk, whey, peptonized milk or albumin water usually being suitable. The beef extracts, meat juices, and artificially prepared protein foods are unnecessary, and sometimes harmful. Water should be given freely at fixed intervals. It is desirable to have the patient take at least four litres of water daily and larger amounts are an advantage. This causes polyuria, and is a sort of internal hydrotherapy by which the toxins are washed out. Barley water, lemonade, soda water, or iced-tea may be used. It is doubtful if alcohol is of any value except when its use enables the patient to take nourishment more freely.

Special care must be given to the mouth, which should be cleaned after each feeding. A mouth wash should be used freely (such as phenol 3 i, 4 c. c., glycerine 3 i, 30 c. c., and boric acid, saturated solution, to 3 x, 300 c. c.).

(c) HYDROTHERAPY.—The use of water, inside and outside, was no new treatment in fevers at the end of the eighteenth century, when James Currie (a friend of Burns and the editor of his poems) wrote his Medical Reports on the Effects of Water, Cold and Warm, as a Remedy in Fevers and other Diseases. In the United States it was used with great effect and recommended

strongly by Nathan Smith, of Yale. The value of bathing in fevers was especially emphasized by the late Dr. Brand, of Stettin.

Hydrotherapy may be carried out in several ways, of which the most satisfactory are sponging, the wet pack, the ice-rub, and the full bath.

(1) *Sponging*.—The water may be tepid or cold, according to the height of the fever. A thorough sponge-bath should take from fifteen to twenty minutes. The cold sponging and the ice-rub are not quite as formidable as the full bath, for which, when there is an insuperable objection in private practice, they are excellent alternatives. But frequently it is difficult to get the friends to appreciate the advantages of the sponging. When such is the case, and in children and delicate persons, it can be made a little less formidable by sponging limb by limb and then the back and abdomen.

(2) The *wet pack* is not so generally useful in typhoid fever, but in cases with very pronounced nervous symptoms, if the tub is not available, the patient may be wrapped in a sheet wrung out of water at 60° or 65°, and then cold water sprinkled over him with an ordinary watering-pot.

(3) *The Bath*.—The tub should be long enough so that the patient can be completely covered except his head. Our rule has been to give a bath every third hour when the temperature is above 102.5°. The patient remains in the tub for fifteen or twenty minutes, is taken out, wrapped in a dry sheet, and covered with a blanket. While in the tub the limbs and trunk are rubbed thoroughly, either with the hand or with a suitable rubber. It is well to give the first one or two baths at a temperature of 80° to 85°. There is no routine temperature and that between 70° and 85° which suits best is chosen. It is important to see that the canvas supports are properly arranged, and that the rubber pillow is comfortable for the patient's head. The amount of complaint made by the patient is largely dependent upon the skill and care with which the baths are given. The blueness and shivering, which may follow the bath, are not serious features. Contra-indications are peritonitis, hæmorrhage, phlebitis, abdominal pain, and great prostration.

The good effects of the baths are: (i) The influence on the nervous system; delirium lessens, tremor diminishes and toxic features are less marked. (ii) Increased excretion by the kidney. (iii) The tonic effect on the circulation; the heart rate falls, the pulse becomes smaller and harder, and the blood-pressure rises. Vaso-motor paresis is lessened. (iv) With hydrotherapy the initial bronchitis is benefited, and there is less chance of passive congestion of the lungs. (v) The liability to bed-sores is diminished and the frequent cleansing of the skin is beneficial. Should boils occur, one tub should be used for that patient alone. (vi) Reduction of the temperature may occur but is not an important effect. (vii) The mortality is reduced. In general hospitals from six to eight patients in every hundred are saved by this plan of treatment. At the Brisbane Hospital, where F. E. Hare used it so thoroughly, the mortality was reduced from 14.8 to 7.5 per cent. There is a remarkable uniformity in the death-rate of institutions using the method—usually from 6 to 8 per cent.

(d) MEDICINAL TREATMENT.—There is no specific drug treatment, but it is usually advisable to give hexamine after the second week, twenty to thirty grains (1.3 to 2 gm.) daily. In private practice it may be safer, for the young practitioner especially, to order an acid or a mild fever mixture. The ques-

tion of medicinal antipyretics is important: they are used far too often and too rashly in typhoid fever. The giving of antiseptic drugs intravenously does not seem justified. Quinine in moderate doses is sometimes given but its value is doubtful. In the various intestinal antiseptic drugs we have no faith. Most of them do no harm, except that their use too often diverts the practitioner from more rational and safer courses.

(e) VACCINE AND SERUM THERAPY.—The value of treatment by vaccines during the height of the disease has not been proved. Various forms of vaccines are used and given subcutaneously or intravenously. Doses varying from 50 to 500 million bacilli are given, usually three or four days apart. A moderate reaction should be produced. As patients react very differently, the smaller doses are safer at first, especially if given intravenously. Gay reports good results from the intravenous injection of sensitized vaccine sediment. His initial dose is $1/50$ mg., corresponding to 150 million bacteria. In long-continued attacks when progress is slow, for complications due to the presence of typhoid bacilli in organs or tissues, and for carriers, vaccine therapy is helpful. No serum of proved value has been obtained.

(f) TREATMENT OF SPECIAL SYMPTOMS.—For severe toxæmia water should be given freely by mouth if possible, otherwise by the bowel or subcutaneously. Hydrotherapy should be used actively, best by tub baths. For headache and delirium an ice-bag or cold compresses should be kept to the head. If the patient is delirious and restless a dose of morphia hypodermically is the best treatment. Lumbar puncture is also useful, the fluid being allowed to run as long as it flows under pressure. Every delirious patient should be constantly watched. It is important to secure sleep for these patients, for which morphia is most reliable. Hydrotherapy, internal and external, is our greatest aid in the treatment of the nervous conditions. The abdominal pain and tympanites are best treated with fomentations or turpentine stupes. The latter, if well applied, give great relief. Sir William Jenner used to lay great stress on the advantages of a well-applied turpentine stupe applied as follows: A flannel roller was placed beneath the patient, and then a double layer of thin flannel, wrung out of very hot water, with a dram of turpentine mixed with the water, was applied to the abdomen and covered with the ends of the roller. When the stomach is greatly distended the passage of a stomach tube gives relief. When the gas is in the large bowel, a rectal tube may be passed or a turpentine enema given. For tympanites, with a dry tongue, turpentine may be given, ℥ xv (1 c. c.) every three hours. Whey and albumen-water should be substituted for milk. Pituitary extract or eserine $\frac{1}{50}$ gr. (0.0013 gm.) hypodermically, may be tried. Opium should not be given.

For the diarrhœa, if severe—that is, if there are more than three or four stools daily—a starch and opium enema may be given; or, by the mouth, a combination of bismuth, in large doses, with Dover's powder; or the acid diarrhœa mixture, acetate of lead (gr. ii, 0.13 gm.), dilute acetic acid (℥ xv, 1 c. c.), and acetate of morphia (gr. $\frac{1}{6}$, 0.01 gm.). Repeated saline irrigations are sometimes helpful. The amount of food should be reduced, and whey and albumen-water in small amounts substituted for the milk. An ice-bag or cold compresses relieve the soreness which sometimes accompanies diarrhœa.

Constipation is present in many cases and it is well to give an ordinary enema every second day. The addition of turpentine (℥ ss, 15 c. c.) is advisa-

ble if there is meteorism. Mineral oil, one-half to one ounce a day, may be given.

Hæmorrhage.—As absolute rest is essential, the greatest care should be taken in the use of the bed-pan. Ice may be given and a light ice-bag placed on the abdomen. The amount of food should be restricted for eight or ten hours. If there is a tendency to collapse, stimulants should be given. Injection of salt solution beneath the skin or into a vein should only be done in case of emergency. Turpentine is warmly recommended by certain authors. Should opium be given? One-fifth of the cases of perforation occur with hæmorrhage, and opium may obscure the features upon which the diagnosis of perforation may be made. Opium increases any tendency to tympanites. We have abandoned the use of opium. The injection of human or horse serum (10 to 20 c. c.) is of value. Transfusion should be done in serious cases. Sodium citrate given intravenously shortens the coagulation time, reaching a maximum in one hour and returning to normal in twenty-four hours. A 30 per cent. solution is used; 3 to 6 c. c. being injected very slowly, taking from ten to fifteen minutes. Its use is contraindicated in hæmorrhagic blood diseases in which the platelets are decreased. Calcium lactate may be given in doses of 15 grains (1 gm.) three times a day.

Perforation and Peritonitis.—Early diagnosis and early operation mean the saving of one-third of the cases of this otherwise fatal complication. The aim should be to operate for the perforation, and not to wait until general peritonitis diminishes the chances of recovery. An incessant, intelligent watchfulness on the part of the medical attendant and the early co-operation of the surgeon are essentials. Every case of more than ordinary severity should be watched with special reference to this complication. Thorough preparation by early observation, careful notes, and knowledge of the conditions will help to prevent needless exploration. No case is too desperate; we had a recovery after three operations. Twenty cases of perforation in our series were operated upon with seven recoveries. In doubtful cases it is best to operate, as the patients stand an exploration very well.

Cholecystitis.—A majority of the cases recover, but if the symptoms are very severe and progressive, operation should be advised. For chronic cholecystitis hexamine should be given in large doses and the vaccine treatment employed; if not successful operation should be done. Duodenal biliary drainage may be given a trial.

With signs of failure of the circulation, hydrotherapy should be carried on actively and strychnine given hypodermically (gr. $\frac{1}{50}$ to $\frac{1}{20}$, 0.001 to 0.003 gm.) every three hours. Saline infusions (500 c. c.) are useful especially if the patient is not taking much water by mouth. Digitalis may be given as the tincture (℥ xv, 1 c. c.) but if collapse or severe symptoms occur, strophanthin gr. $\frac{1}{100}$ (0.00065 gm.) intramuscularly is better. For collapse, epinephrine (℥ xv, 1 c. c. of the 1-1000 solution) should be given intramuscularly. The bath treatment is the best preventive of circulatory failure. For phlebitis the limb should be kept absolutely at rest and wrapped in raw cotton. The application of a sedative lotion may relieve pain.

Bacilluria.—When bacilli are present, hexamine may be given in ten-grain (0.65 gm.) doses and kept up, if necessary, for several weeks. If the urine is alkaline sodium benzoate, gr. x (0.6 gm.) should be added. A patient should

not be discharged with bacilli in his urine. Pyelitis should be treated in the same way, large amounts of water being given. For cystitis, irrigations of bichloride of mercury (1/100,000 solution and gradually increased in strength) may be given.

For orchitis, mastitis, parotitis, etc., an ice-bag should be applied. Incision and drainage are advisable on the first signs of suppuration. Vaccine treatment may be helpful.

In protracted cases special care should be taken to guard against bed-sores. Absolute cleanliness and careful drying of the parts after an evacuation should be enjoined. Pressure should be avoided by the use of rubber rings. The patient should be turned from side to side and propped with pillows, and the back sponged with alcohol.

Bone Lesions.—The use of a typhoid vaccine is well worthy of trial. Typhoid periostitis does not always go on to suppuration, though, as a rule, it requires operation. This should be done very thoroughly and the diseased parts completely removed, as otherwise recurrence is inevitable. For typhoid spine fixation by a plaster jacket or some form of apparatus is advisable. Trauma should be guarded against. In the milder cases active counter-irritation is useful. If pain is severe, large doses of sedatives are necessary.

(g) CONVALESCENCE.—The diet can be gradually increased, but it is usually best to wait at least a week after the temperature is normal before giving ordinary meats or coarse vegetables. Solid food sometimes disagrees if it is given too early. Whether an error in diet may cause relapse is doubtful. The patient may be allowed to sit up for a short time about the end of the first week of convalescence, and the period may be prolonged with a gradual return of strength. He should move about slowly, and when the weather is favorable should be in the open air as much as possible. He should be guarded at this period against all unnecessary excitement. Emotional disturbance not infrequently is the cause of recrudescence of the fever. Constipation is not uncommon in convalescence and is best treated by mineral oil by mouth and enemata. A protracted diarrhoea, usually due to ulceration in the colon, may retard recovery. In such cases the diet should be restricted to milk and the patient confined to bed; large doses of bismuth and astringent injections will prove useful. The recrudescence of the fever does not require special measures. The treatment of the relapse is essentially that of the original attack.

Post-typhoid insanity requires the care of an expert. The patients usually recover. The swollen leg after phlebitis is a source of great worry. A bandage or a well-fitting elastic stocking should be worn during the day. The outlook depends on the completeness with which the collateral circulation is established. In a good many cases there is permanent disability.

The post-typhoid neuritis, a cause of much alarm and distress, usually gets well, though it may take months, or even a couple of years, before the paralysis disappears. After the subsidence of the acute symptoms systematic massage of the paralyzed and atrophic muscles is the best treatment.

Typhoid Carriers.—Treatment of these is difficult. Hexamine should be given persistently and in large doses. Drainage or removal of the gall bladder and X-ray exposures over it have been successful in some cases. The employment of an autogenous vaccine offers the best chance of success. Doses increas-

ing from 25 to 1,000 or 1,500 million bacilli are given at intervals of 10 days. Carriers should not be allowed to handle or prepare food.

Lastly, no patient should be discharged from observation until we are certain that he can not infect others.

II. PARATYPHOID FEVER

Definition.—An acute infection caused by the *Bacillus paratyphosus* of which there are several varieties, A, B, C and D: A and B are the most common. They are closely related to the typhoid bacillus and cause a clinical picture much like typhoid fever.

History.—In 1896 Achard and Bensaude reported a case of “typhoid fever” in which they found an organism which was not *B. typhosus* and to which they gave the name of paratyphoid. In 1898 Gwyn isolated an organism to which he gave the name of paracolony bacillus. In 1902 Buxton described the two varieties A and B. Since then many reports on this disease have been made and the experience of the Great War added much to our knowledge of these infections.

Occurrence.—Before the recent war paratyphoid A was more common in the United States and paratyphoid B in Europe. In the recent war the relative proportions varied in different places, but as a rule the B form was the more common. As regards the relative incidence of typhoid and paratyphoid fever in soldiers, one army series of 4,218 cases showed 1,684 of typhoid and 2,534 of paratyphoid fever, and in another series of 5,700 cases, 93 per cent. were paratyphoid. The inoculation in the majority had been against typhoid fever only.

Etiology.—The paratyphoid organisms differ from *B. typhosus* in cultural and agglutination properties. The A form is nearer to the typhoid bacillus and the B form closer to *B. suipestifer* and *enteritidis*. The general problems of infection are the same as those of typhoid fever with particular importance on the part played by carriers, especially in paratyphoid B. The B form at times occurs in a form suggesting meat poisoning.

Pathology.—The toxins of the paratyphoid organisms do not show the same tendency to attack lymphoid tissues as the toxin of the typhoid bacillus and appear to cause a greater variety of lesions elsewhere. As there is a bacteraemia there is a possibility of any part of the body being attacked. In general the intestinal lesions are much like those of typhoid fever but show a tendency to superficial necrosis rather than to deep ulceration. In some cases the intestines are acutely inflamed without involvement of the lymphoid tissue. Some statistics suggest that the colon frequently shows ulceration. Hæmorrhage and perforation are not so common as in typhoid fever. There are several forms: (1) A septicaemia with little or no change in the bowels; (2) cases not distinguishable from ordinary typhoid; (3) a dysenteric form, in which the lesions are chiefly in the large bowel, and (4) cases in which the lesions are particularly in one part of the body. In Dawson and Whittington's study of 17 fatal cases, in 10 the large bowel was involved.

Symptoms.—The average incubation period is about ten days and an acute onset is common. Headache and abdominal pain may occur at the onset, to be followed by the usual signs of an infection, malaise, chilly sensations,

and general pains. Bronchitis is common early in the attack. The clinical features are variable, as in typhoid fever, and various forms have been described depending on the predominant symptoms, such as typhoid, septicæmic, dysenteric, biliary, urinary, respiratory, arthritic, etc. Apathy is often marked, especially early, and severe headache is common. The striking point about the fever curve is the irregularity. It may be of the classical typhoid type with remissions beginning about the end of the second week, the duration of fever may be short, there may be constant remissions or the fever may be irregular throughout. The pulse rate is usually slow and with a rising temperature may be a suggestive point. The blood pressure is usually low. The rash is generally like the roseola of typhoid fever, but sometimes consists of large irregular spots, raised and not fading completely on pressure, leaving areas of pigmentation. It is sometimes general. Sweating is common especially in patients with a remittent type of fever. The spleen is usually enlarged. Intestinal disturbance may be marked, more particularly at the onset, especially in the B form. Hæmorrhage is rarely profuse and perforation is rare. Relapse rarely occurs. The course as a rule is shorter than in typhoid fever. Some writers comment on the slow improvement after the acute features are over and emphasize mental depression in convalescence.

Complications.—These are much like those of typhoid fever with more tendency to involvement of the respiratory tract, jaundice with infection of the bile passages, nephritis, abscess formation and arthritis. The sequelæ are the same as typhoid fever, even to the bone lesions.

Diagnosis.—For practical purposes typhoid and paratyphoid fever may be considered as one disease; clinically the diagnosis is based on the same findings and only a bacteriological diagnosis can be regarded as absolutely beyond doubt. The agglutination tests are fairly reliable if markedly positive.

Prognosis.—In civil life the death rate is very low, about one per cent., but in the armies it was higher.

Prophylaxis.—This is the same as for typhoid fever and the use of preventive inoculation has had the same success. The triple vaccine (typhoid and both paratyphoids) should be used. The importance of carriers should be kept in mind.

Treatment.—This is the same as in typhoid fever.

III. COLON BACILLUS INFECTIONS

The colon bacillus, or more properly speaking the group of colon bacilli, in their biological and pathological peculiarities are closely related to the organisms of the typhoid group. Normal inhabitants of the intestines, where in all probability they serve a useful function, the *Bacillus coli* may be taken as the typical member of the group. There are great difficulties in determining the extent of the lesions caused by this organism, which varies extraordinarily in virulence. To it has been attributed a host of maladies from appendicitis to old age, but more conservative pathologists limit its pathogenic scope. It is not easy to separate the effects of the *B. coli* from those of other organisms with which it is so often associated. The needful bacteriological distinction must be considered in connection with agglutination tests.

A. General Hæmic Infections.—There are several groups of cases:

(a) Terminal Infections.—After death the colon bacillus swarms in the body, invading the blood and contaminating all parts. In protracted illnesses, in acute intestinal and peritoneal affections it may be present in the blood some time before death and may be responsible for the terminal fever.

(b) Cases resembling typhoid fever. The onset may be with a chill followed by fever, often irregular, and leucocytosis. Jaundice occurs relatively often. Toxaemia may be marked. The diagnosis depends on blood cultures.

(c) Cases of general infection with secondary abscesses.

(d) Secondary infection in other diseases, as for example typhoid fever.

B. Sub-infections.—Adami suggested that a number of chronic diseases have their origin in a mild, continuous infection with *B. coli* and he brought forward evidence to show that such affections as anaemia and cirrhosis of the liver may be due to it. Metchnikoff induced the lesions of early cirrhosis and of arterio-sclerosis by administering the products of the growth of the *B. coli*. The question is far from settled.

C. Local Infections.—Here we are on safer ground and have definite lesions produced by the organism.

(a) Peritonitis.—In perforation of the bowel, in strangulated hernia, in obstruction, in various types of ulcer, the peritonitis may be due to *B. coli*.

(b) Cholecystitis and cholangitis, either of the simple catarrhal type or suppurative, may be caused by it.

(c) Infection of the Urinary Tract.—The bladder and the pelvis of the kidneys are chiefly affected. There are three possible channels of infection—by the ureter, the blood stream, and the lymphatics. Hæmatogenous infection is the most common but lymphatic infection from the bowel plays an important rôle in many cases. Bowel troubles have been present and with slight abrasion of the mucosa of the colon the bacilli may enter the lymphatics. An interesting point is the relative frequency of involvement of the right kidney; Franke states that the cæcum and ascending colon are connected by a train of lymphatics with the right kidney, an anatomical communication not present with the left. The general features may be marked, with chills, high fever, toxæmia and delirium. The fever is variable but may continue for days, more or less constant or remittent. There is often pain referred to the region of the kidney, which is tender and may be found to be enlarged. There may be well-marked hæmaturia; the urine contains pus in varying amount and colon bacilli are present. The course varies greatly and the fever may continue for one or two weeks. Relapse is common and many cases become chronic with acute exacerbations at intervals. Some of the patients manifest general ill health and others suffer from urinary tract symptoms. The pus in the urine varies in amount from time to time. There are several groups of cases.

(1) In children, in whom it is not uncommon. In Jeffrey's study of 60 cases at the Hospital for Sick Children a large proportion occurred in females (53). Death followed in 9 cases. (2) In connection with pregnancy. The cases are common and important and may occur at any time during pregnancy or follow delivery. The pelvis of the right kidney is most often attacked. (3) As a secondary infection in other diseases, especially typhoid fever. (4) The group in adults, in whom, without any obvious cause, and in the majority without any previous intestinal trouble, acute pyelitis or pyelocystitis comes

on. The infection is obstinate and a distressing sequel is a chronic arthritis. (5) Cystitis and urethritis in newly married women are sometimes due to colon infection. Care should be taken not to regard them as gonorrhœal. The colon bacillus is often present in the urethra of the female.

(d) Intestines.—To the *Bacillus coli* almost all the diseases of the bowels from ulcer of the duodenum to appendicitis have been attributed. Gastric and duodenal ulcers have been produced by feeding cultures of *B. coli* to dogs, and from the peptic ulcers of young infants Helmholtz isolated the organism in pure culture. There is great difficulty in determining the precise etiological relationship of *B. coli* to the lesions of the gastro-intestinal tract.

(e) Other local infections with which the *colon bacillus* has been associated are acute meningitis, abscess of the brain, endocarditis, and suppuration in various parts. Only in a small proportion of these cases has the association been demonstrated by cultural and biological tests.

TREATMENT.—In the cases of general infection, rest, careful diet, and large amounts of water are indicated. It is well to give a low protein diet, meat and eggs being excluded. To influence the intestinal flora, *B. acidophilus* cultures may be tried. Buttermilk in place of raw milk is useful. The bowels should be kept open and a daily enema is usually advisable. The milder laxatives are best, such as cascara and salines. In the local infections the treatment is that of the condition present, as peritonitis and cholecystitis. For infection of the urinary tract the diet should be simple and large amounts of water should be given with urinary antiseptics, especially hexamine (gr. 40 to 60 a day, 2.6 to 4 gm.) or hexyl-resorcinol (0.15 gm.). Local treatment by irrigations is helpful in cystitis and in some cases of pyelitis. The use of an autogenous vaccine is an aid in some cases and should always be tried in sub-acute and chronic cases. The initial dose should be small (one-half or one million organisms) and gradually increased to 250 million or even more. Every effort should be made to improve the general health and special attention given to insure regularity of the bowels.

IV. THE PYOGENIC INFECTIONS

(*Sapræmia, Septicæmia, Pyæmia, Focal Infection, Terminal Infections*)

Definition.—A group of non-specific diseases, induced by a number of micro-organisms, of which the pyogenic cocci are the most important, characterized by fever, chills, leucocytosis, often a profound intoxication and sometimes by foci of suppuration. A hard-and-fast line can not be drawn between an infection and an intoxication, but agents of infection alone are capable of reproduction, whereas those of intoxication are toxins, some of which are produced by bacteria, or by vegetable and animal cells. There are five chief clinical types of pyogenic infection:

1. LOCAL INFECTIONS WITH THE DEVELOPMENT OF TOXINS

This is the common mode of invasion of certain infectious diseases. Tetanus, diphtheria and erysipelas are diseases which have sites of local infection in which the pathogenic organisms develop; but the constitutional

effects are caused by the absorption of the poisonous products. The diphtheria toxin produces all the general symptoms, the tetanus toxin every feature of the disease, without the presence of their respective bacilli. Certain of the symptoms following the absorption of the toxins are general to all; others are special and peculiar, according to the organism which produces them. A chill, fever, general malaise, prostration, rapid pulse, restlessness, and headache are the most frequent. With but few exceptions the febrile disturbance is the most common feature. The most serious effects are upon the nervous system and the circulation, and the gravity of the changes in these systems is to some extent a measure of the intensity of the toxæmia.

2. SEPTICÆMIA

Formerly, and in a surgical sense, the term "septicæmia" was used to designate the invasion of the blood and tissues of the body by the organisms of suppuration, but in the medical sense the term may be applied to any condition in which, with or without a local site of infection, there is microbic invasion of the blood and tissues, but without metastatic foci of suppuration. Owing to the development of bacteria in the blood, this condition is termed *bacteræmia*. The main forms of streptococci concerned are the *S. pyogenes* or *hæmolyticus* and *S. viridans*. The former usually produces general infections, often from a definite portal of entry as a wound or the uterus. The latter is often from infected teeth and the most common example is subacute bacterial endocarditis.

(a) Progressive Septicæmia from Local Infection.—The common streptococcus and staphylococcus infection is, as a rule, first local, and the toxins alone pass into the blood. In other instances the cocci appear in the blood and throughout the tissues, causing a septicæmia which intensifies greatly the severity of the case. The clinical features of this form are well seen in the cases of puerperal septicæmia or in dissection wounds, in which the course of the infection may be traced along the lymphatics. The symptoms usually set in within twenty-four hours, and rarely later than the third or fourth day. There is a chill or chilliness, with moderate fever at first, which gradually rises and is marked by daily remissions and even intermissions. The pulse is small and compressible, and may reach 120 or higher. Gastro-intestinal disturbances are common, the tongue is red at the margin, and the dorsum is dry and dark. Diarrhœa occurs often, especially in streptococcus infections. There may be early delirium or marked mental prostration and apathy. As the disease progresses there may be pallor of the face or a yellowish tint. Capillary hæmorrhages are not uncommon. Anæmia is common and leucocytosis usually occurs.

In streptococcus cases we now recognize that these infections are not always so serious as we thought. Death may occur within twenty-four hours or be delayed for several days, even for weeks, and recovery may occur. One patient showed streptococci in the blood for six weeks, but recovered (Cole). On post-mortem examination there may be no gross focal lesions in the viscera, and the seat of infection may present only slight changes. The spleen is enlarged and soft, the blood may be extremely dark in color, and hæmorrhages are common, particularly on the serous surfaces. Neither thrombi nor em-

boli are found. Certain clinical features occur with streptococcus infection, chiefly the absence of delirium, a rather abnormal mental acuteness, and the presence of a greater degree of anæmia. Staphylococcus infections more often show secondary lesions, especially in the pleura, peritoneum, bones and joints.

Many instances of septicæmia are combined infections; thus in diphtheria streptococcus septicæmia is a common, and the most serious, event. The local disease and the symptoms produced by absorption of the toxins dominate the clinical picture; but the features are usually much aggravated by the systemic invasion. These secondary septicæmias are caused most frequently by the streptococcus, but may be due to other bacteria.

(b) Septicæmia without Recognizable Local Infection.—*Cryptogenetic Septicæmia.*—The subjects when attacked may be in perfect health; more commonly they are already weakened by acute or chronic illness. The pathogenic organisms are varied. *Streptococcus pyogenes* is the most common; the forms of staphylococcus more rare. Other occasional causal agents are the pneumococcus, *Bacillus proteus*, *Bacillus pyocyaneus* and *Bacillus influenzae*. In a period of three years, from the medical wards of the Hopkins Hospital, 21 cases of general infection came to autopsy, of which 13 were due to *Streptococcus pyogenes*, 2 to *Staphylococcus pyogenes*, and 6 to the pneumococcus. In 19 of these cases the patients were already the subjects of some other malady, which was aggravated, or in most instances terminated, by the septicæmia. The symptoms vary somewhat with the character of the micro-organisms. In the streptococcus cases there may be chills with high, irregular fever, and a more characteristic septic state than in the pneumococcus infection.

These cases come correctly under the term “cryptogenetic septicæmia” as employed by Leube, inasmuch as the local focus of infection is not evident during life and may not be found after death. Although most of these cases are terminal infections, yet there are instances of this type of affection coming on in apparently healthy persons. The fever may be extremely irregular, characteristically septic, and persist for many weeks. Foci of suppuration may not develop, and may not be found even at autopsy. There are cases of an intermittent pyrexia persisting for weeks, in which it is impossible to give any explanation of the phenomena, with ultimate recovery and in which tuberculosis and malaria can be excluded. These cases require to be carefully studied bacteriologically. Local symptoms may be absent, though there may be enlargement of the liver, in some due to a diffuse suppurative hepatitis. The pyocyanic disease, or cyano-pyæmia, is an interesting form of infection with *Bacillus pyocyaneus*, of which a number of cases have been reported.

3. SEPTICO-PYÆMIA

The pathogenic micro-organisms which invade the blood and tissues may settle in certain foci and there cause suppuration. When multiple abscesses are thus produced in connection with a general infection, the condition is known as pyæmia or, perhaps better, septico-pyæmia. There are no specific organisms of suppuration, and pyæmia may be produced by organisms other than streptococci and staphylococci, though these are the most common. Other forms which may invade the system and cause foci of suppuration are the

pneumococcus, the gonococcus, *B. coli*, *B. typhosus*, *B. proteus*, *B. pyocyaneus*, *B. influenzae*. In a large proportion of all cases of pyæmia there is a focus of infection, a suppurating external wound, an osteomyelitis, a gonorrhœa, an otitis media, an empyema, or an area of suppuration in a lymph-gland or about the appendix. In a large majority of all these cases the common pus cocci are present.

In a suppurating wound, for example, the pus organisms induce hyaline necrosis in the smaller vessels with the production of thrombi and purulent phlebitis. The entrance of pus organisms in small numbers into the blood does not necessarily produce pyæmia. Commonly the transmission to various parts from the local focus takes place by the fragments of thrombi which pass as emboli to different parts, where, if the conditions are favorable, the pus organisms excite suppuration. A thrombus which is not septic or infected, when dislodged and impacted in a distant vessel, produces at most only a simple infarction; but, coming from an infected source and containing pus microbes, an independent centre of infection is established wherever the embolus may lodge. These independent suppurative centres in pyæmia, known as *embolic* or *metastatic abscesses*, have the following distribution:

(a) In external wounds, in osteomyelitis, and in acute phlegmon of the skin, the embolic particles very frequently excite suppuration in the lungs, producing wedge-shaped pyæmic infarcts; from these, or rarely by paradoxical embolism, or direct passage of bacteria or minute emboli through the pulmonary capillaries, metastatic foci of inflammation may occur in other parts.

(b) Suppurative foci in the territory of the portal system, particularly in the intestines, produce metastatic abscesses in the liver with or without suppurative pylephlebitis.

Endocarditis is very liable to occur in all forms of septicæmia, and modifies materially the character of the clinical features. Streptococci and staphylococci are the most common organisms in the vegetations, but pneumococci, gonococci, tubercle bacilli, typhoid bacilli, and other forms have been isolated. The vegetations which grow at the site of the valve lesion become covered with thrombi, particles of which may be dislodged and carried as emboli to different parts of the body, causing multiple abscesses or infarcts.

Symptoms of Septico-pyæmia.—In a case of wound infection, prior to the onset of the characteristic symptoms, there may be signs of local trouble, and in the case of a discharging wound the pus may change in character. The onset of the disease is marked by a severe rigor, during which the temperature rises to 103° or 104° and is followed by a profuse sweat. These chills are repeated at intervals, either daily or every other day. In the intervals there may be slight pyrexia. The constitutional disturbance is marked and there are loss of appetite, nausea, and vomiting, and, as the disease progresses, rapid emaciation. Local symptoms usually occur. If the lungs become involved there are dyspnoea and cough. The physical signs may be slight. Involvement of the pleura and pericardium is common. The anæmia, often profound, causes great pallor of the skin, which later may be bile-tinged. The spleen is enlarged, and there may be intense pain in the side, pointing to perisplenitis from embolism. Usually in the rapid cases a typhoid state supervenes, and the patient dies comatose.

Skin Lesions.—These are very numerous. *Erythema*, the so-called “surgical scarlet fever,” may extend from the infected wound or appear on the face or chest and spread widely. *Purpura* occurs as a widespread lesion in all hyper-intense types of septicæmia and is met with in the later stages as a remarkable discrete rash in various parts of the body. In the acute purpura of septicæmia the skin may be completely covered within 36 hours, usually preceded by a dusky erythema. *Pustules*, *vesicles*, *ecthyma*, *urticaria* and *papular rashes* are occasional complications. Ordinary herpes is rare.

In the chronic cases the disease may be prolonged for months; the chills recur at long intervals, the temperature is irregular, and the condition of the patient varies from month to month. The course is usually slow and progressively downward.

Diagnosis.—*Septicæmia* and *pyæmia* are frequently overlooked and often mistaken for other affections. Cases following a wound, an operation, or parturition are readily recognized. On the other hand, the following conditions may be overlooked:

Osteo-mycelitis.—Here the lesion may be limited, the constitutional symptoms severe, and the course of the disease very rapid. The cause of the trouble may be discovered only post mortem.

So, too, acute septicopyæmia may follow *gonorrhœa* or a *prostatic abscess*.

Cases are sometimes confounded with *typhoid fever*, particularly the more chronic instances, in which there are *diarrhœa*, *great prostration*, *delirium*, and *irregular fever*. The spleen, too, is often enlarged. The marked leucocytosis is an important differential point.

In some of the instances of *ulcerative endocarditis* the diagnosis is very difficult, particularly in what is known as the typhoid, in contradistinction to the septic type. In *acute miliary tuberculosis* the symptoms may resemble those of septicæmia, more commonly those of typhoid fever.

The *post-febrile arthritides*, such as occur after scarlet fever, are really instances of *mild septic infection*. The joints may sometimes suppurate and pyæmia develop. So, also, in *tuberculosis of the kidneys* and *calculous pyelitis* recurring rigors and sweats due to *septic infection* are common. In some latitudes septic and pyæmic processes are too often confounded with *malaria*. In early tuberculosis, or even when signs of excavation are present in the lungs, and in cases of suppuration in various parts, particularly empyema and abscess of the liver, the diagnosis of malaria is made. The practitioner may take it as a safe rule, to which he will find very few exceptions, that *an intermittent fever which resists quinine is not malaria*.

Other conditions which may be mistaken for pyæmia are *profound anæmia*, *infective sinus thrombosis*, certain cases of *Hodgkin's disease*, *cholecystitis*, the hepatic intermittent fever associated with *gall-stones in the common duct*, rare cases of *essential fever in nervous women*, *perinephritic abscess*, and the fever sometimes seen in *rapidly growing cancer*.

Treatment.—(a) GENERAL.—Nourishment should be given liberally in the form of liquids and soft foods up to 3,000 calories with 80 grams of protein a day. Water should be forced and it is well to give it by the bowel or subcutaneously if there is any difficulty in taking it by mouth. The bowels should be kept open by simple laxatives. Hydrotherapy by tub baths is useful. Sedatives should be given for sleep.

(b) **SURGICAL.**—In pyæmia, when the pus is accessible, free evacuation and drainage is often the only treatment required. The primary focus should be treated if possible. Unfortunately, in only too many cases the focus of infection is not accessible; it then is a septicæmia, and for such cases we have the treatment with serums and vaccines.

(c) **VACCINE AND SERUM TREATMENT.**—By blood cultures or by cultures from the focus of infection the organism is isolated, and an autogenous vaccine prepared. The use of vaccines in acute infections is not without risk and this treatment should be employed only after careful consideration. The giving of a stock vaccine containing one or many organisms is to be condemned. Blood transfusion is indicated for severe anæmia. The transfusion of blood from a donor who has been given vaccines made from cultures from the patient, in the hope of introducing antibodies, is not advised. There is a risk of sudden death following the transfusion. In acute streptococcus cases the ordinary antistreptococcus serum or one of the polyvalent serums may be used. Good results are sometimes obtained.

(d) **DRUGS.**—There are none which control septic fever. The coal-tar products and quinine are of doubtful service. The intravenous injection of antiseptic drugs has not proved to be of value in the past but mercurochrome-220 and gentian violet may be more useful. Arsenic is worthy of a thorough trial, best in the form of sodium cacodylate (gr. i, 0.06 gm. daily) given intramuscularly or intravenously.

4. FOCAL INFECTION

A local focus of infection may be the source of acute septicæmia, but in addition a variety of chronic infections may arise with distant and important manifestations. The resulting infection may be either local or general. The importance and frequency of focal sepsis have been emphasized in recent years and it gives the clue to the etiology of many obscure conditions. Foci of infection may be primary and secondary. The latter are usually the result of infection through the blood or lymph.

Etiology.—The organism most often concerned is some variety of streptococcus of which there are two main types, *S. pyogenes (hæmolyticus)* and *S. viridans* being examples. The former is responsible for the more acute infections; the latter causes more subacute and chronic disturbances and plays a large part in the etiology of subacute endocarditis. The colon bacillus is sometimes responsible. The local focus may be open to the surface or closed. An example of the former is seen in pyorrhœa alveolaris and of the latter in the closed abscess at the root of a tooth. The local infection may be situated in many parts of the body but in a majority the situation is in the mouth or tonsils. Investigation has shown the frequency of deep tonsillar infection, which may show no indication on the surface, and of suppuration about the roots of teeth. Infection of the skin, nose or sinuses, bronchi, bile-ducts, gall-bladder, appendix, intestine, pelvic organs and the urinary tract may be the source.

Pathology.—The lesions may be varied and situated in almost any part of the body. Perhaps the most frequent sites are in the joints and fibrous tissues. Arthritis and fibrositis are common and many of the obscure pains,

termed myalgia, neuritis, "chronic and muscular rheumatism," are due to fibrositis secondary to a focal infection. Among other lesions are hyperthyroidism, endocarditis, myocarditis, gastric ulcer, cholecystitis, appendicitis and nephritis. The resulting disturbance is due to absorbed toxins or to bacteria which reach the blood stream or lymph and are carried to other parts. Systemic intoxication from absorption is not rare. The lesions produced do not show any particular characteristic. In general they are those of a chronic inflammatory process with occasional acute exacerbations, but on the whole tending to chronicity. The organisms are usually of low virulence. The disparity between the frequency of foci of infection and resulting disease is apparently largely due to natural resistance and immunity.

Symptoms.—These can not be stated in detail as so many different structures may be involved. In general, there are some statements that can be made. (1) The condition is usually chronic and may vary much from time to time. Thus secondary arthritis is generally sub-acute or chronic, although there are cases with an acute course and more with acute exacerbations. (2) The onset of symptoms may be determined by some intercurrent disease or debilitating condition. (3) The general health is apt to be affected. (4) Active reaction as shown by marked fever is unusual, as the process is too chronic. (5) There is a tendency to anæmia and disturbance of nutrition.

Diagnosis.—This can not be stated in any exact terms. The first essential is the recognition of the important part that focal infection plays. Chronic arthritis and fibrositis are not primary maladies; they are secondary to infection somewhere. We know that if a patient has gonorrhœal arthritis there is a primary local process. The primary focus has often to be searched for; it may give no symptoms. This may involve the examination of many organs. If there is no localizing indication, the teeth and tonsils may be examined first. The nose and sinuses, bronchi, gall bladder, etc., have all to be considered. Duodenal cultures are important in the recognition of biliary tract infection. Nor is it safe to conclude that a focus when found is the sole responsible one for there may be multiple foci.

Prognosis.—Many factors enter into this, especially the resistance of the individual and the virulence of the organism. The degree of anatomical change must be considered, thus if extensive joint changes have occurred the removal of a focus of infection can not alter these although it may prevent further damage. Naturally the earlier proper treatment is instituted the better the outlook.

Treatment.—(1) Removal of the cause, the focus of infection. This demands proper diagnosis and should not be done until this is as definite as possible. A man with mouth infection may have the real focus in his prostate. Caution should be exercised in the treatment of foci if the general symptoms are acute. (2) Vaccine therapy. In some cases this is of value and, if possible, an autogenous vaccine should be used. (3) Injection of non-specific protein, for example fifty millions of killed typhoid bacilli intravenously. This has proved useful, particularly in cases of chronic arthritis, but is to be employed with caution. (4) Helping the patient's powers of resistance by attention to the general health. Fresh air and sunlight, sufficient food, and proper treatment for anæmia, are indicated.

5. TERMINAL INFECTIONS

There is truth in the paradoxical statement that persons rarely die of the disease with which they suffer. Secondary *terminal* infections carry off many incurable cases. Flexner analyzed 255 cases of chronic renal and cardiac disease in which complete bacteriological examinations were made at autopsy. Excluding tuberculous infection, 213 gave positive and 42 negative results. The infections may be local or general. The former are extremely common, and are found in a large proportion of all cases of nephritis, arterio-sclerosis, heart disease, cirrhosis of the liver, and other chronic disorders. Affections of the serous membranes (acute pleurisy, pericarditis, or peritonitis), meningitis, and endocarditis are the most frequent lesions. It is perhaps safe to say that the majority of cases of advanced arterio-sclerosis and of nephritis succumb to these intercurrent infections. The infective agents are very varied. The streptococcus is the most common, but the pneumococcus, and staphylococcus, the proteus, pyocyaneus, and gas bacillus are also found. It is surprising in how many instances of arterio-sclerosis, of chronic heart disease, of nephritis and particularly of cirrhosis of the liver in Flexner's series the fatal event was determined by an acute tuberculosis of the peritoneum or pleura.

The general terminal infections are somewhat less common. Of 85 cases of chronic renal disease in which Flexner found micro-organisms at autopsy, 38 exhibited general infections; of 48 cases of chronic cardiac disease, in 14 the distribution of bacteria was general. Other diseases in which general terminal infection may occur are Hodgkin's disease, leukæmia, and chronic tuberculosis. And, lastly, probably of the same nature is the terminal enterocolitis so frequently met with in chronic disorders.

V. ERYSIPELAS

Definition.—A special pyogenic infection caused by the *Streptococcus erysipelatis*, characterized by inflammation of the skin with fever and toxæmia.

Etiology.—Erysipelas is a widespread affection, endemic in most communities, and at certain seasons epidemic. It is particularly prevalent in the spring and of 2,012 cases collected by Anders, 1,214 occurred during the first five months of the year. April had the largest number of cases. Erysipelas is both infectious and inoculable; but, except under special conditions, the infection is not very virulent and does not seem to act at any great distance. It can be conveyed by a third person. Recurrent attacks occur which may be due to bacterial allergy, there being infection in the sinuses, nose or tonsils.

The disposition to the disease is widespread, but the susceptibility is specially marked in the case of individuals with wounds or abrasions of any sort. Recently delivered women and persons who have been the subjects of surgical operations are particularly prone to it. A wound, however, is not necessary, and in the so-called idiopathic form, although it may be difficult to say that there was not a slight abrasion about the nose or lips, in very many cases there certainly is no observable external lesion. In some cases the infection spreads through the tissues from the nasal cavity to the skin. This is probably comparatively common,

Chronic alcoholism, debility, and nephritis are predisposing agents. Certain persons show a special susceptibility to erysipelas, and it may recur in them repeatedly. There are instances, too, of a family predisposition.

The specific agent of the disease is a streptococcus growing in long chains, which is included under the group name *Streptococcus pyogenes*, with which *Streptococcus erysipelatis* appears to be identical. The fever and constitutional symptoms are due in great part to the toxins; the more serious visceral complications are the result of secondary metastatic infection.

Morbid Anatomy.—Erysipelas is a simple inflammation. In its uncomplicated forms there is seen, post mortem, little else than inflammatory œdema. The cocci are found chiefly in the lymph-spaces and most abundantly in the zone of spreading inflammation. In the uninvolved tissue beyond the inflamed margin they are to be found in the lymph-vessels. In more extensive and virulent forms there may be suppuration. Infarcts occur in the lungs, spleen, and kidneys, and there may be the general evidences of pyæmic infection. Some of the worst cases of malignant endocarditis are secondary to erysipelas; thus, of 23 cases, 3 occurred in connection with this disease. Septic pericarditis and pleuritis also occur. The disease may in rare cases extend to and involve the meninges. Pneumonia is not a very common complication. Acute nephritis is met with, often ingrafted upon an old process.

Symptoms.—The following description applies specially to erysipelas of the face and head, the form of the disease which is most common.

The incubation is variable, probably from three to seven days.

The stage of invasion is often marked by a rigor, and followed by a rapid rise in the temperature and other characteristics of an acute fever. When there is a local abrasion, the spot is slightly reddened; but if the disease is "idiopathic," there is within a few hours slight redness over the bridge of the nose and on the cheeks. The swelling and tension of the skin increase and within twenty-four hours the external symptoms are well marked. The skin is smooth, tense, and œdematous. It looks red, feels hot, and the superficial layers of the epidermis may be lifted as small blebs. The patient complains of a feeling of tension in the skin; the swelling rapidly increases; and during the second day the eyes are usually closed. The first-affected parts gradually become pale and less swollen as the disease extends at the periphery. When it reaches the forehead it progresses as an advancing ridge perfectly well defined and raised; and often, on palpation, hardened extensions can be felt beneath the skin which is not yet reddened. Even in a case of moderate severity, the face is enormously swollen, the eyes are closed, the lips greatly œdematous, the ears thickened, the scalp is swollen, and the patient's features are unrecognizable. The formation of blebs is common on the eyelids, ears, and forehead. The cervical lymph-glands are swollen, but are usually masked in the œdema of the neck. The temperature keeps high without marked remissions for four or five days and then defervescence takes place by crisis. Leucocytosis is present. The general condition of the patient varies much with his previous state of health. In old and debilitated persons, particularly in alcoholics, the constitutional depression may be very great. Delirium is present, the tongue becomes dry, the pulse feeble, and there is marked tendency to death from toxæmia. In the majority of cases, however, even with extensive lesions, the constitutional disturbance, considering the height of the fever,

is slight. The mucous membrane of the mouth and throat may be swollen and reddened. The process may extend to the larynx, but the severe œdema of this part occasionally met with is commonly due to the extension of the inflammation from without inward. Obstinate diarrhœa is common.

There are cases in which the inflammation extends from the face to the neck, and over the chest, and may gradually migrate or wander over the greater part of the body (*E. migrans*).

Suppuration occurs frequently in facial erysipelas. Small cutaneous abscesses are common about the cheeks, forehead and neck, and beneath the scalp large collections of pus may accumulate. Suppuration seems to occur more frequently in some epidemics than in others, and at the Philadelphia Hospital in one year nearly all the cases in the erysipelas wards presented local abscesses.

Complications.—*Meningitis* is rare. The cases in which death occurs with marked brain symptoms do not usually show, post mortem, meningeal affection. *Pneumonia* is an occasional complication. *Ulcerative endocarditis* and *septicæmia* are more common. *Albuminuria* is almost constant, particularly in persons over fifty. *Phlebitis* and *nephritis* are occasionally seen. Da Costa called attention to curious irregular returns of the fever which occur during convalescence without any aggravation of the local condition.

Diagnosis.—This rarely presents any difficulty. The mode of onset, the rapid rise in fever, and the characters of the local disease are distinctive. In *cellulitis* the swelling is more brawny and a definite edge is lacking. In old patients with chronic disease there may be areas of redness and swelling, especially on the legs, which are difficult to diagnose. If in doubt treat them as erysipelas.

Prognosis.—Healthy adults rarely die. The mortality in hospitals is about 7 per cent.; in private practice about 4 per cent. (Anders). In the new-born, when the disease attacks the navel, it is almost always fatal. In drunkards, in nephritic patients, and in the aged erysipelas is a serious affection, and death may result from a complication or from toxæmia. The wandering erysipelas, which has a more protracted course, may cause death from exhaustion.

Treatment.—Isolation should be strictly carried out, particularly in hospitals. A practitioner in attendance upon a case of erysipelas should not attend cases of confinement.

The disease is self-limited and a large majority of the cases get well without any internal medication. The diet should be nutritious and light. Large amounts of water should be given. For the restlessness, delirium, and insomnia, chloral or the bromides may be given; or, if these fail, opium. When the fever is high the patient may be bathed or sponged, or phenacetine or acetyl-salicylic acid (gr. v, 0.3 gm.) may be given.

Antitoxin.—This was introduced by Birkhaug (1926). The dose must be governed partly by the severity of the attack; 25 c. c. intramuscularly is an average amount repeated daily as long as necessary. Intravenous administration should be used only if the condition is desperate. The reports as to the value of this treatment are in general favorable.

Attention should be paid to any focus of infection, as in a sinus or in the tonsils. In patients with recurring attacks active immunization may be attempted by gradually increasing doses of *S. erysipelatis* vaccine.

Of local applications, ichthyol (as a salve, 1 to 4 of lanolin), bichloride of mercury solution (1 to 5,000), salicylic acid (1 to 500), phenol in oil (5 per cent.), a saturated solution of magnesium sulphate, powdered stearate of zinc, collodion, or ichthyol in collodion (1 to 4), may be used. Painting the skin ahead of the advancing area with tincture of iodine is sometimes effectual. Perhaps as good an application as any is cold water, which was highly recommended by Hippocrates. If the disease involves the eyelids boric acid compresses should be applied and one or two drops of argyrol solution (10 per cent.) instilled several times a day.

VI. DIPHTHERIA

Definition.—A specific infectious disease, characterized by a local fibrinous exudate, usually upon the mucous membrane of the throat, and by constitutional symptoms due to toxins produced at the site of the lesion. The presence of the diphtheria bacillus is the etiological criterion by which true diphtheria is distinguished from other forms of membranous inflammation.

Cases of angina, diagnosed as diphtheria, may be due to other organisms and to these the term diphtheroid is applied. Though usually milder, severe constitutional disturbance, and even paralysis, may follow these forms.

History.—Known in the East for centuries, and referred to in the Babylonian Talmud, it is not until the first century A. D. that an accurate clinical account appears in the writings of Aretæus. The paralysis of the palate was recognized by Ætius (sixth century A. D.). Throat pestilences are mentioned in the Middle Ages. Severe epidemics occurred in Europe in the sixteenth and seventeenth centuries, particularly in Spain. In England in the latter part of the eighteenth century it was described by Fothergill and Huxham, and in America by Bard. Washington died of the disease. Ballonius recognized the affection of the larynx and trachea in 1762; Home in Scotland described it as croup. The modern description dates from Bretonneau, of Tours (1826), who gave to it the name *diphthérie*. Throughout the nineteenth century it prevailed extensively in all known countries. After innumerable attempts, in which Klebs took a leading part, the organism was isolated by Loeffler. The toxin was determined by the work of Roux, Yersin, and others, and finally the antitoxin was discovered by Behring (1891). Schick (1913) described the intradermal test for susceptibility and immunity.

Etiology.—Everywhere endemic in large centres of population, the disease becomes at times epidemic. In England and Wales in 1928, 3,191 persons died of the disease. In the registration area in the United States the death-rate per 100,000 has fallen from 43 in 1900 to 7.8 in 1925. In the tropics it is not a very serious disease. Dry seasons seem to favor the disease, which shows an autumnal prevalence.

MODES OF INFECTION.—The disease is highly infectious. The bacilli may be transmitted (a) from one person to another; few diseases have proved more fatal to physicians and nurses. (b) Infected articles may convey the bacilli, which may remain alive for many months; scores of well-attested instances have been recorded of this mode of transmission. (c) Persons suffering from atypical forms of diphtheria may convey the disease; nasal catarrh, mem-

branous rhinitis, mild tonsillitis, and otorrhœa may be caused by diphtheria bacilli, and from each of these sources cases have been traced. (d) From the throats of healthy contacts—diphtheria carriers, persons who present no signs of the disease—the bacilli have been obtained by culture. (e) Even healthy children without any naso-pharyngeal catarrh, who have not been in contact with the disease, may harbor the bacilli. Cultures from children show a varying percentage of positive results but the majority are non-virulent forms. Only persons who harbor the virulent forms are capable of transmitting the disease. In schools the interchange of articles, such as sweets, pencils, etc., and the habit which children have of putting everything into their mouths afford endless opportunities for the transmission of the disease. (f) Numerous epidemics have been traced to milk. Virulent bacilli have been found in milk and Dean and Todd and Ashby found virulent organisms in the acquired lesions on the teats of cows. (g) A few instances of accidental infection from cultures and through animals are on record.

PREDISPOSING CAUSES.—Age is the most important. Sucklings are not often attacked, but Jacobi saw three cases in the new-born. Early in the second year the disposition increases rapidly, and continues at its height until the fifth year. At Baginsky's clinic, Berlin, among 2,711 cases, 1,235 occurred from the second to the fifth years inclusive. In New York between 1891-1900 among the deaths 80.8 per cent. occurred under five, 17 per cent. between five and ten—figures which show the extraordinary preponderance of the disease among children. Girls are attacked in slightly larger numbers than boys. November, December, and January are the months of greatest prevalence in the United States; in London October and November. Children in the higher circles and those in small communities and in the country are more susceptible than those living in the crowded quarters of cities.

Individual susceptibility is a very special factor; not only do many of those exposed escape, but even those, too, in whose throats virulent bacilli lodge and grow. Probably about 80 per cent. of all adults have antitoxin in the blood and so are protected. The Schick reaction is of great value in determining immunity. A negative reaction indicates the presence of antitoxin as when it is not present the toxin causes a reaction. The amount of toxin injected intradermically in the right forearm is $\frac{1}{40}$ M.L.D. in 0.2 c. c. of salt solution. A control test is made on the other arm (toxin inactivated by heat). Four reactions may result: 1. *Negative.* There is no reaction on either arm. 2. *Positive.* The right arm shows an area of erythema and slight infiltration, which reaches its height in four days and persists for seven to ten days. The control test shows nothing. 3. *Negative pseudoreaction.* This is of an anaphylactic character, and is the same on both arms. It reaches its height in 24 to 36 hours and disappears about the third day. 4. *Positive combined.* This is a combination of 2 and 3. A reaction is present on both arms but in two days the left has faded and the right arm shows the usual positive test about the fourth day. In young children the reactions are usually definitely negative or positive.

The *B. diphtheriæ* is found chiefly in the false membrane. Post mortem the bacilli may be found in the blood and internal organs. Occasionally they are found in the blood during life. It may be the predominating or sole organism in the common broncho-pneumonia. The Klebs-Loeffler bacillus

has been found in diphtheritic conjunctivitis, in otitis media, sometimes in wound diphtheria, upon the genitals, in fibrinous rhinitis, and in ulcerative endocarditis.

Morphological Characters.—The bacillus is non-motile, varies from 2 to 6 μ in length and from 0.3 to 0.8 μ in thickness. In appearance it is multi-form, varying from short, rather sharply pointed rods to irregular bizarre forms, with one or both ends swollen, and staining more or less unevenly and intensely. Virulent and non-virulent forms are alike. The toxicity test in the guinea-pig is necessary to distinguish them. The bacillus is Gram-positive.

The bacillus is very resistant, and cultures have been made from a bit of membrane preserved for five months in a dry cloth. Incorporated with dust and kept moist, the bacilli were still cultivable at the end of eight weeks; kept in a dried state they no longer grew at the end of this period (Ritter).

The Presence of the Diphtheria Bacillus in Non-membranous Angina and in Healthy Throats.—The bacillus has been isolated from cases which show nothing more than a simple catarrhal angina of a mild type without any membrane, with diffuse redness, and perhaps huskiness and signs of catarrhal laryngitis. In other cases the anatomical picture may be that of a lacunar tonsillitis. The organisms may be met with in perfectly healthy throats (diphtheria carriers), particularly in persons in the same house, or the ward attendants and nurses in fever hospitals. Following an attack of diphtheria the bacilli may persist in the throat or nose after all the membrane has disappeared for weeks or months. In explanation Councilman called attention to the frequency with which the antrum is affected.

Toxins.—Roux and Yersin showed that a fatal result following the inoculation with the bacillus was not caused by extension of the micro-organisms within the body; and they were able to separate the toxin from the bacilli. The toxin so separated killed with very much the same effects as those caused by the inoculation of the bacilli; the pseudo-membrane, however, is not formed. Susceptible animals may be rendered immune from diphtheritic infection by injecting weakened cultures of the bacillus or suitable doses of the diphtheria toxin. The result is a febrile reaction which soon passes away and leaves the animal less susceptible to the toxin or the living bacilli. By repeating and gradually increasing the quantity of toxin injected a high degree of immunity can be produced in large animals.

Bacteria Associated with the Diphtheria Bacillus.—The most common is the Streptococcus pyogenes. Others, in addition to the organisms constantly found in the mouth, are the pneumococcus, the bacillus coli, and the staphylococcus aureus and albus. Of these, probably the streptococcus is the most important, as cases of general infection with this organism have been found in diphtheria. The suppuration in the lymph-glands and the broncho-pneumonia are usually caused by this organism.

Pseudo-Diphtheria Bacillus.—The Klebs-Loeffler bacillus varies very much in its virulence, and may exist in a form entirely devoid of pathogenic properties. This organism should not be designated pseudo-diphtheria bacillus. The name should be confined to bacilli, which, though resembling the diphtheria bacillus morphologically and culturally, do not produce diphtheria toxin. They may be found both in healthy and diseased throats. Another bacillus, showing certain cultural differences from the pseudo-diphtheria

bacillus, has been found in the conjunctival sac in health and disease (*B. xerosis*). *Hoffmann's bacillus*, which is also spoken of as pseudo-diphtheria bacillus, is a common organism in the throats of healthy persons and is found also in cases of diphtheria; but how far it is responsible for pathological conditions is not settled. *Vincent's bacillus* is a fusiform organism associated with a diphtheroid angina (Vincent's angina), which occurs in two forms: a membranous and an ulcerative and destructive. The fusiform bacilli have been found in healthy throats and also in association with true diphtheria.

Diphtheroid Inflammations.—Under the term *diphtheroid* may be grouped those membranous inflammations which are not associated with the Klebs-Loeffler bacillus. It is a more suitable designation than pseudo-diphtheria or secondary diphtheria. Streptococci and pneumococci are the organisms most often found. The proportion of cases of diphtheroid inflammation varies greatly in the different statistics. Of the observations made by Park and Beebe (5,611) in New York, 40 per cent. were diphtheroid. Figures from other sources do not show so high a percentage. Of 450 cases (Park and Beebe), 300 occurred in the autumn months and 150 in the spring; 198 occurred in children from the first to the seventh year. In a large proportion of all the cases the disease develops in children, and can be differentiated from diphtheria proper only by the bacteriological examination. It may be simply an acute catarrhal angina with lacunar tonsillitis. Some of the cases are due to *Hoffmann's bacillus*, a few to *Vincent's fusiform bacillus*. The diphtheroid inflammations are particularly prone to develop in connection with the acute fevers.

(a) *Scarlet Fever*.—In a large proportion of the cases of angina in scarlet fever the Klebs-Loeffler bacillus is not present but streptococci are usually found. Where diphtheria is prevalent, a large proportion of the cases of membranous throats in scarlet fever may be genuine diphtheria.

(b) *Measles*.—Membranous angina is much less common in this disease. It occurred in 6 of the 450 diphtheroid cases in New York.

(c) *Whooping-cough* may be complicated with membranous angina. Escherich records 4 cases, the Klebs-Loeffler bacillus being found in all.

(d) *Typhoid Fever*.—Membranous inflammations in this disease are not very infrequent; they may occur in the throat, the pelvis of the kidney, the bladder, or the intestines. The complication may be caused by the Klebs-Loeffler bacillus, but it is frequently a streptococcus infection.

Clinical Features of the Diphtheroid Affection.—The cases, as a rule, are milder, and the mortality is low, only 2.5 per cent. in the 450 cases of Park and Beebe. The diphtheroid inflammations complicating the specific fevers are often very fatal, and a general streptococcus infection is not infrequent. As in the Klebs-Loeffler angina, there may be only a simple catarrhal process. In other instances the tonsils are covered with a creamy, pultaceous exudate, without any actual membrane. An important group may begin as a simple lacunar tonsillitis, while in others the entire fauces and tonsils are covered by a continuous membrane, and there is a foul sloughing angina with intense constitutional disturbance.

Are the diphtheroid cases infectious? General clinical experience warrants the statement that the membranous angina associated with the fevers is rarely communicated to other patients. The health department of New

York does not keep the diphtheroid cases under supervision. Park and Beebe say that "it did not seem that the secondary cases were any less liable to occur when the primary case was isolated than when it was not."

Sequelæ of the Diphtheroid Angina.—The usual mildness of the disease is in part, no doubt, due to the less frequent systemic invasion. Some of the worst forms of general streptococcus infection are, however, seen in this disease. There are no peculiarities, local or general, which are distinctive; and even the most extensive paralysis may follow an angina caused by it.

Morbid Anatomy.—**DISTRIBUTION OF MEMBRANE.**—A definite membrane was found in 127 of the 220 fatal Boston cases, distributed as follows: tonsils, 65 cases; epiglottis, 60; larynx, 75; trachea, 66; pharynx, 51; mucous membrane of nares, 43; bronchi, 42; soft palate, including uvula, 13; œsophagus, 12; tongue, 9; stomach, 5; duodenum, 1; vagina, 2; vulva, 1; skin of ear 1; conjunctiva, 1. An interesting point in the Boston investigation was the great frequency with which the accessory sinuses of the nose were found to be infected. In the fatal cases, the exudation is very extensive, involving the uvula, the soft palate, the posterior nares, and the lateral and posterior walls of the pharynx. These parts are covered with a dense pseudo-membrane, in places firmly adherent, in others beginning to separate. In extreme cases the necrosis is advanced with a gangrenous condition. The membrane is of a dirty greenish or gray color, and the tonsils and palate may show necrotic sloughing. The erosion may be deep enough in the tonsils to open the carotid artery, or a false aneurism may be produced in the deep tissues of the neck. The nose may be completely blocked by the membrane, which may extend to the conjunctivæ and through the Eustachian tubes into the middle ear. In laryngeal diphtheria the exudate in the pharynx may be extensive. In many cases it is slight upon the tonsils and fauces and abundant upon the epiglottis and the larynx, which may be completely occluded. In severe cases the exudate extends into the trachea and to the smaller bronchi.

In all these situations the membrane varies very much in consistence, depending greatly upon the stage at which death has taken place. If death has occurred early, it is firm and closely adherent; if late, it is soft, shreddy, and readily detached. When firmly adherent it is torn off with difficulty and leaves an abraded mucosa. In the most extreme cases, in which there is extensive necrosis, the parts look gangrenous. In fatal cases the lymphatic glands of the neck are enlarged, and there is a general infiltration of the tissues with serum; the salivary glands, too, may be swollen. In rare instances the membrane extends to the gullet and stomach.

The primary lesion is a necrosis and degeneration of the epithelial tissues. The organisms grow, not in the living, but in the necrotic tissues. The first step is a necrosis of the epithelium, often preceded by active proliferation of the nuclei of the cells, which become changed into refractive hyaline masses. From the structures below an inflammatory exudate rich in fibrin factors is poured out, and fibrin is formed when this comes in contact with the necrotic epithelium.

The following are the important changes in the other organs:

HEART.—If death occurs in the first week the muscle is pale and there is loss of striation. Later there is œdema both of the fibres and interstitial tissue. The bundle of His shows marked changes followed by mononuclear

infiltration. At later periods there is interstitial myocarditis, to which some cases of fibrous myocarditis may be due. Fatty change is not marked. Pericarditis and endocarditis are rare; endocarditis was present in 7 of 220 cases at the Boston City Hospital. The diphtheria bacilli have been found in the vegetations.

The PULMONARY COMPLICATIONS are important, and death is due to them as often as to the throat lesion. Broncho-pneumonia, or, as Councilman terms it, acinous pneumonia, is the most common, and was present in 131 of the 220 Boston cases; lobar pneumonia is rare. The pneumococcus is the principal agent in the lung infections but streptococci and diphtheria bacilli are frequently met with.

KIDNEYS.—The lesions, which are due to the action of the toxins, not to the presence of bacteria, vary from simple degeneration to an intense nephritis. There is no specific type of lesion. Interstitial and glomerular nephritis are most common in the older subjects. Degenerative changes are present in a large proportion of all the fatal cases. The liver and spleen show the degenerative lesions of acute infections.

Symptoms.—The period of incubation is “from two to seven days, oftenest two.” The initial symptoms are those of an ordinary febrile attack—slight chilliness, fever, and aching pains in the back and limbs. In mild cases the symptoms are trifling, and the child may not feel ill enough to go to bed. The temperature is very variable and bears no relation to the severity of the attack; in the worst cases there may be normal or subnormal temperature. In young children there may be convulsions at the outset.

PHARYNGEAL DIPHTHERIA.—In a typical case there is at first redness of the fauces and the child complains of slight difficulty in swallowing. The membrane first appears upon the tonsils, and it may be difficult to distinguish a patchy diphtheritic pellicle from the exudate of the tonsillar crypts. The pharyngeal mucous membrane is reddened, and the tonsils themselves are swollen. By the third day the membrane has covered the tonsils, the pillars of the fauces, and perhaps the uvula, which is thickened and oedematous, and may fill completely the space between the swollen tonsils. The membrane may extend to the posterior wall of the pharynx. At first grayish-white in color, it changes to a dirty gray, often to a yellow-white. It is firmly adherent, and when removed leaves a bleeding, slightly eroded surface, which is soon covered by fresh exudate. The glands in the neck are swollen and may be tender. The general condition of a patient in a case of moderate severity is usually good; the temperature not very high, in the absence of complications ranging from 102° to 103° F. The pulse range is from 100 to 120. The local condition of the throat is not of great severity, and the constitutional depression is slight. The symptoms gradually abate, the swelling of the neck diminishes, the membranes separate, and from the seventh to the tenth day the throat becomes clear and convalescence sets in.

Clinically atypical forms are common, and we follow Koplik's division:

- (a) There may be no local manifestation of membrane, but a simple catarrhal inflammation associated sometimes with a croupy cough. The detection in these cases of the diphtheria bacillus can alone determine the diagnosis. Such cases are of great moment, inasmuch as they may communicate the severer disease to other children.

(b) There are cases in which the tonsils are covered by a pultaceous exudate, not a consistent membrane.

(c) Cases presenting a punctate form of membrane, isolated, and usually on the surface of the tonsils.

(d) Cases which begin and often run their entire course with the local picture of a typical lacunar tonsillitis. They may be mild, and the local exudate may not extend, but in other cases there is rapid development of membrane, and extension of the disease to the pharynx and the nose, with severe septic and constitutional symptoms.

(e) Under the term "latent diphtheria" Heubner has described cases, usually secondary, occurring chiefly in hospital practice, in young persons the subject of wasting affections, such as rickets and tuberculosis. There are fever, naso-pharyngeal catarrh, and gastro-intestinal disturbances.

(f) A hæmorrhagic form is sometimes seen with severe toxæmia and hæmorrhages into the skin and mucous membranes.

SYSTEMIC INFECTION.—The constitutional disturbance in mild diphtheria is very slight and there are instances of extensive local disease without grave systemic symptoms. As a rule, the general features bear a definite relation to the severity of the local disease. There are rare instances in which from the outset the constitutional prostration is extreme, the pulse frequent and small, the fever high, and the nervous phenomena are pronounced; the patient may sink in two or three days overwhelmed by the intensity of the toxæmia. There are cases of this sort in which the exudate in the throat may be slight, but usually the nasal symptoms are pronounced. The temperature may be very slightly raised or even subnormal. More commonly the severe systemic symptoms appear at a later date when the pharyngeal lesion is at its height. They are constantly present in extensive disease, and when there is a sloughing, fetid condition. The lymphatic glands become greatly enlarged; the pallor is extreme; the face has an ashen-gray hue; the pulse is rapid and feeble, and the temperature sinks below normal. In the most aggravated forms there are gangrenous processes in the throat, and in rare instances, extensive sloughing of the tissues of the neck.

Escherich accounts for the discrepancy sometimes observed between the severity of the constitutional disturbance and the intensity of the local process, by assuming varying degrees of susceptibility to the diphtheria bacillus on the one hand, and to its toxin on the other hand. With high local susceptibility to the bacillus, with little general susceptibility to the toxin, there is extensive local exudate with mild constitutional symptoms, or *vice versa*, severe systematic disturbance with limited local inflammation.

A leucocytosis is present in diphtheria. Morse does not think it of any prognostic value, since it is present and may be pronounced in mild cases.

NASAL DIPHTHERIA.—In cases of pharyngeal diphtheria the Klebs-Loeffler bacillus is found on the mucous membrane of the nose and in the secretions, even when no membrane is present, but it may produce two affections similar locally but widely differing in their general features.

In membranous or fibrinous rhinitis, a very remarkable affection seen usually in children, the nares are occupied by thick membranes, but there is an entire absence of any constitutional disturbance. Ravenel collected 77 cases,

in 41 of which a bacteriological examination was made, in 33 the Klebs-Loeffler bacillus being present. All the cases ran a benign course, and in all but a few the membrane was limited to the nose, and the constitutional symptoms were absent or very slight. Remarkable and puzzling features are that the disease runs a benign course, and that infection of other children in the family is extremely rare.

On the other hand, nasal diphtheria is apt to present a most malignant type of the disease. The infection may be primary in the nose, and in one case there was otitis media, and the Klebs-Loeffler bacillus was separated from the discharge before the condition of nasal diphtheria was suspected. While some cases are of mild character, others are very malignant, and the constitutional symptoms most profound. The glandular inflammation is usually very intense, owing, as Jacobi points out, to the great richness of the nasal mucosa in lymphatics. From the nose the inflammation may extend through the tear-ducts to the conjunctivæ and into the antra.

LARYNGEAL DIPHTHERIA (*Membranous Croup*).—With a very large proportion of all the cases of membranous laryngitis the Klebs-Loeffler bacillus is associated; in a smaller number other organisms, particularly the streptococcus, are found. Of 286 cases in which the disease was confined to the larynx or bronchi, in 229 the Klebs-Loeffler bacilli were found. The streptococcus cases are more likely to be secondary to other acute diseases. Laryngeal diphtheria is rare in adults.

Symptoms.—Naturally, the clinical symptoms are almost identical in the non-specific and specific forms of membranous laryngitis.

The affection begins like an acute laryngitis with slight hoarseness and rough cough, to which the term croupy has been applied. After these symptoms have lasted for a day or two with varying intensity, the child suddenly becomes worse, usually at night, and there are signs of impeded respiration. At first the difficulty in breathing is paroxysmal, due probably to more or less spasm of the muscles of the glottis. Soon the dyspnœa becomes continuous, inspiration and expiration become difficult, particularly the latter, and with the inspiratory movement the epigastrium and lower intercostal spaces are retracted. The voice is husky and may be reduced to a whisper. The color gradually changes and the imperfect aëration of the blood is shown in the lividity of the lips and finger-tips. Restlessness comes on and the child tosses from side to side, vainly trying to get breath. Occasionally, in a severer paroxysm, portions of membrane are coughed out. The fever is rarely very high and the condition of the child is usually good at the time of the onset. The pulse is increased in frequency and is small if cyanosis be present. In favorable cases the dyspnœa is not very urgent, the color of the face remains good, and after one or two paroxysms the child goes to sleep and wakes in the morning, perhaps without fever and feeling comfortable. The attack may recur the following night with greater severity. In unfavorable cases the dyspnœa becomes more and more urgent, the cyanosis deepens, the child, after a period of intense restlessness, sinks into a semi-comatose state, and death finally occurs from asphyxia or toxæmia. In other cases the onset is less sudden and is preceded by a longer period of indisposition. As a rule, there is pharyngeal infection. The constitutional disturbance may be more severe, the fever higher, and there may be swelling of the glands of the neck. In-

spection of the fauces may show the presence of false membrane on the pillars or tonsils. Bacteriological examination alone can determine whether these are due to the diphtheria bacillus or to the streptococcus. Fagge held that non-contagious membranous croup may spread upward from the larynx just as diphtheritic inflammation is in the habit of spreading downward from the fauces. Ware, of Boston, whose essay on croup is one of the most solid contributions to the subject, reported the presence of exudate in the fauces in 74 out of 75 cases of croup. In protracted cases pulmonary symptoms may occur, which are sometimes due to the difficulty in expelling the muco-pus from the tubes; in others, the false membrane extends into the trachea and bronchi. During the paroxysm the vesicular murmur is scarcely audible, but the laryngeal stridor may be loudly communicated.

DIPHThERIA OF OTHER PARTS.—Primary diphtheria occurs occasionally in the conjunctiva. It follows in some instances the affection of the nasal mucous membrane. Some of the cases are severe and serious, but it has been shown that the diphtheria bacilli may be present in a conjunctivitis catarrhal in character, or associated with only slight membranous deposits.

Diphtheria of the external auditory meatus is seen when a diphtheritic otitis media has extended through the tympanic membrane.

Diphtheria of the skin is most frequently seen in the severer forms of pharyngeal diphtheria, in which the membrane extends to the mouth and lips, and invades the adjacent portions of the skin of the face. The skin about the anus and genitals may also be attacked. Pseudo-membranous inflammation is not uncommon on ulcerated surfaces and wounds. In very many of these cases it is a streptococcus infection, but in a majority, perhaps, in which the patient is suffering with diphtheria, the Klebs-Loeffler bacillus will be found in the fibrinous exudate. As proposed by Welch, the term "wound diphtheria" should be limited to infection of a wound by the Klebs-Loeffler bacillus. Paralysis may follow wound diphtheria. The fibrinous membrane so common in the neighborhood of the tracheotomy wound in diphtheria is rarely associated with the Klebs-Loeffler bacillus. Diphtheria of the genitals is occasionally seen in both sexes.

Complications and Sequelæ.—Of local complications, hæmorrhage from the nose or throat may occur in the severe ulcerative cases. Skin rashes are not infrequent, particularly the diffuse erythema. Occasionally there is urticaria and in the severe cases purpura. Fatal cases almost invariably show broncho-pneumonia and large patches of collapse, or the septic particles may reach the bronchi and excite gangrenous processes which may lead to severe and fatal hæmorrhage. Jaundice, usually a feature of the toxæmia, is rarely of serious import. Local gangrene may occur.

Albuminuria, present in all severe cases, is alarming only when the albumin is in considerable quantity and associated with epithelial or blood casts. Nephritis may appear quite early, setting in occasionally with complete suppression of urine. In comparison with scarlet fever the renal changes lead less frequently to general dropsy. In rare instances there may be coma, and even convulsions, without albumin in the urine, and without dropsy.

Of the sequelæ, paralysis due to toxic neuritis, is by far the most important. It can be experimentally produced in animals by the inoculation of

the toxins. The proportion of the cases in which it occurs ranges from 10 to 15 and even to 20 per cent. It usually comes on in the second or third week of convalescence. It may follow very mild cases; indeed, the local lesion may be so trifling that the onset of the paralysis calls attention to the true nature of the trouble. It is proportionately less frequent in children than in adults. J. D. Rolleston's study indicates that the early use of antitoxin diminishes the liability to paralysis. In 494 cases collected by Woodhead, the palate was involved in 155, the ocular muscles in 197, in 10 other muscles. Ninety-one of the patients died.

Of the local paralyses the most common is that which affects the palate. This gives a nasal character to the voice, and, owing to a return of liquids through the nose, causes a difficulty in swallowing. The palate is relaxed and motionless, and the sensation in it is also much impaired. The affection may extend to the constrictors of the pharynx, and deglutition become embarrassed. Within two or three weeks or even a shorter time the paralysis disappears. In many cases the palate affection is part of a general neuritis. Of other local forms perhaps the most common are paralyses of the eye-muscles, intrinsic and extrinsic. There may be strabismus, ptosis, and loss of power of accommodation. Facial paralysis is rare. The neuritis may be confined to the nerves of one limb, though more commonly the legs or the arms are affected together. Very often with the palatal paralysis is associated a weakness of the legs without definite palsy but with loss of the knee-jerk. In diaphragmatic paralysis, from involvement of the phrenic nerve, the breathing is intercostal, the diaphragm is high in position and the abdomen scaphoid. It usually occurs about the sixth week and is almost always fatal. An ataxic paralysis sometimes occurs with inco-ordination of movements and loss of muscle sense. It may be mistaken for tabes dorsalis.

The multiple form of diphtheritic neuritis may begin with the palatal affection, or with loss of power of accommodation and loss of the tendon reflexes. This last is an important sign, which may occur early, but is not necessarily followed by other signs of neuritis. There is paraplegia, which may be complete or involve only the extensors of the feet. The paralysis may extend and involve the arms and face and render the patient entirely helpless. The muscles of respiration may be spared. Sensory is less common than motor disturbance.

Heart.—Myocardial changes are common and may be serious. The blood pressure often falls markedly. An increase in the heart rate is common early in the attack. In a study of 242 cases S. C. Smith found irregularity from the sixth to the eighth day in 28 per cent. The majority were cases of sinus arrhythmia and sino-auricular block, and a much smaller number showed premature contractions, usually auricular. Heart block of high grade may occur not infrequently and its possibility should always be in mind. The murmurs, so common in children with fever, as a rule are not important. Tachycardia which is persistent, especially with gallop rhythm and a feeble first sound, is of serious omen. A rapid drop in rate to 40, 30 or 20 (heart block) is always ominous, especially if accompanied by vomiting without evident cause. Attacks of acute circulatory failure occur with marked change in the pulse, præcordial pain, rapid respiration and cyanosis. Death may occur very suddenly. Experimental evidence is against the vasomotor centre

being involved. Possibly in some of the cases there is degeneration of the vagus, which is supported by the frequency of paralysis of the palate with vomiting and epigastric pain and tenderness.

Diagnosis.—The presence of the Klebs-Loeffler bacillus is regarded as the sole criterion of true diphtheria, and as this organism may be associated with all grades of throat affections, from a simple catarrh to a sloughing, gangrenous process, it is evident that in many instances there will be a striking discrepancy between the clinical and the bacteriological diagnosis.

The bacteriological diagnosis is simple. The plan adopted by the New York Health Department is a model which may be followed with advantage. The directions are: "The patient should be placed in a good light, and, if a child, properly held. In cases where it is possible to get a good view of the throat, depress the tongue and rub the cotton swab gently but freely against any visible exudate. In other cases, including those in which the exudate is confined to the larynx, avoiding the tongue, pass the swab far back and rub it freely against the mucous membrane of the pharynx and tonsils. Without laying the swab down, withdraw the cotton plug from the culture tube, insert the swab, and rub that portion of it which has touched the exudate gently but thoroughly all over the surface of the blood-serum. Do not push the swab into the blood-serum, nor break the surface in any way. Then replace the swab in its own tube, plug both tubes, put them in the box, and return the culture outfit at once." The culture-tubes are kept at 37° C. for twelve hours and are then ready for examination. An immediate diagnosis may be possible by making a smear preparation of the exudate. The Klebs-Loeffler bacilli may be present in sufficient numbers, and may be quite characteristic.

Where a bacteriological examination can not be made, the practitioner must regard as suspicious all forms of throat affections in children, and carry out measures of isolation and treatment. In this way alone can serious errors be avoided. It is not, of course, in the severer forms of infection that mistake is likely to occur, but in the milder forms, many of which are due to the Klebs-Loeffler bacillus. Acute tonsillitis is usually bilateral and the exudate is rarely marked. The temperature is generally higher than in diphtheria. Vincent's angina may resemble diphtheria closely, having a membrane which may extend to the soft palate. A form of tonsillitis due to mycotic infection, most common in the tropics, simulates diphtheria as the membrane may extend to the palate, pharynx and larynx. In all these the smears and cultures usually give the diagnosis. Syphilis with marked throat involvement has caused difficulty, especially if the tonsils are swollen and show patches. The findings elsewhere, negative cultures and a positive Wassermann reaction are important.

A large proportion of the cases of diphtheroid inflammation of the throat are due to streptococci. They are usually milder, and the liability to general infection is less intense; still, in scarlet fever and other specific fevers most virulent cases of throat disease, with intense systemic infection, are caused by this organism. These streptococcus cases are probably less numerous than the figures given would indicate. Careful examinations in the diphtheria pavilions of hospitals, particularly in Europe, have shown that in the large majority of cases admitted the Klebs-Loeffler bacillus is present. The diag-

nosis between scarlet fever and diphtheria is discussed in the section on scarlet fever.

Laryngeal diphtheria offers many difficulties, and signs of laryngitis in a child should always suggest its possibility. If membrane can be seen in the pharynx or on the epiglottis or diphtheria bacilli obtained by a swab the diagnosis is clear. Any sputum should be examined for portions of membrane. Direct examination of the larynx is of great help if it can be done. Laryngitis due to various causes and laryngismus stridulus may cause doubt and it may be impossible to be sure until longer observation and cultures give aid. In such cases antitoxin should be given at once if there is any doubt. Edema of the larynx, a foreign body in the larynx or trachea and retro-pharyngeal abscess are possible causes of difficulty.

Prognosis.—The outlook depends greatly on the promptness and thoroughness with which antitoxin treatment is carried out. In hospital practice the mortality was formerly from 30 to 50 per cent. In the Boston City Hospital the death-rate between 1888 and 1894 was only once below 40 per cent., and in 1892 and 1893 rose to nearly 50 per cent. Following the introduction of antitoxin from 1895 to 1912 the death-rate has not once been above 15 per cent., and in 6,080 cases was 7.8 per cent. (McCollom). In cases of ordinary severity the outlook is usually good. Extensive membrane, a marked septic state, laryngeal involvement, broncho-pneumonia, evidence of serious myocarditis, nervous system complications, especially bulbar, vomiting, absence of fever and hæmorrhagic features are of serious significance. In children below the age of five years the outlook is more serious as 80 per cent. of the deaths from diphtheria occur in this period. Of late years the mortality has been steadily falling.

Prophylaxis.—Isolation of the sick, disinfection of the clothing and of everything that has come in contact with the patient, careful scrutiny of the milder cases of throat disorder, and more stringent surveillance in the period of convalescence are the essential measures to prevent the spread of the disease. Suspected cases in families or schools should be at once isolated or removed to an infectious hospital. When a death has occurred from diphtheria, the body should be wrapped in a sheet soaked in corrosive sublimate solution (1 to 2,000), and placed in a sealed coffin. The funeral should always be private.

In cases of well-marked diphtheria these precautions are usually carried out, but the chief danger is from the milder cases, particularly the ambulatory form, in which the disease has perhaps not been suspected. But from such patients mingling with susceptible children the disease is often conveyed. The healthy children in a family in which diphtheria exists may carry the disease. The question of the influence of isolation hospitals on the spread of the disease has been solved in Boston, a city which has suffered terribly from diphtheria. The ratio of mortality per 10,000 living in 1893 was 11+, and in 1894 it was 18+. In 1895 the infectious pavilion was opened. Prior to that year only about 10 per cent. of the reported cases were treated in hospital; in succeeding years 50 per cent. were treated in hospital. In 1898 the mortality per 10,000 had fallen to 3, and in 1912 it was 1.5.

A very important matter relates to the period of convalescence as after all the membrane has cleared away, virulent bacilli may persist in the throat

from periods ranging from weeks to months. The disease may be communicated by these carriers and they should be isolated and treated, but there are cases very resistant to all forms of treatment. Antitoxin may be applied locally to the throat and spraying the throat and nose with a culture of lactic acid bacilli is sometimes efficient. The application of iodized phenol (phenol 60, iodine crystals 20, glycerine 20) every second day is sometimes effectual. Removal of the tonsils and adenoids is usually the most efficient measure in those with bacilli in the throat. For carriers with bacilli in the nose mild alkaline douches are useful. The possibility of sinus infection should be considered.

The important elements in the prophylaxis of diphtheria are the rigid scrutiny of the milder types of throat affection, the thorough isolation and disinfection of individual patients and immunization of those who are susceptible to the disease. During an epidemic there should be repeated examinations made of all those exposed to infection to detect carriers. Efforts should be made to educate the public to give early attention to throat and laryngeal symptoms.

Careful attention should be given to the throats and mouths of children, particularly to the teeth and tonsils. Diseased tonsils should be removed. Cats and dogs may carry infection and should be excluded from contact with patients. Physicians and nurses should wear gowns and caps. Everyone coming in contact with the patients should be proved to be immune to the disease.

IMMUNIZATION.—The giving of antitoxin as a preventive measure has an important place. Its value is well shown in the children's hospitals in which it is given as a routine measure. The usual dose for adults is 1,000 units, for older children 750 units, and for children under two years of age 500 units. The immunity lasts about three weeks. The same precautions should be taken as in giving antitoxin to those with the disease.

Toxin-antitoxin.—The value of toxin-antitoxin immunization is thoroughly proved. The ideal would be to immunize all children between the ages of six months and two years as the majority of children are susceptible at the age of one year. At birth about 85 per cent. of infants are immune (derived from the mother), but this immunity usually disappears at the age of six to nine months. Three injections of 1 c.c. each of the toxin-antitoxin mixture are given, one to two weeks apart. The immunity develops slowly (six weeks to three months) and therefore antitoxin should be given in case of exposure to the disease. The immunity persists for at least five years in 98 per cent. of cases (Park) and probably is permanent in many cases. Immunization should not be done in infants below the age of six months. Diphtheria toxoid (anatoxin), diphtheria toxin treated with formaldehyde and which is non-toxic, is coming into more extensive use to produce immunity.

Treatment.—(a) **HYGIENIC MEASURES.**—The patient should be in a room from which the carpets, curtains, and superfluous furniture have been removed. The temperature should be about 68°, and thorough ventilation should be secured. The air may be kept moist by a kettle or a steam-atomizer. If possible, only the nurse, the child's mother, and the doctor should come in contact with the patient. The physician should wear a gown and cap, and on leaving the room he should thoroughly wash his hands and face in corrosive

sublimate solution. The strictest quarantine should be employed against other members in the house.

(b) REST.—This should be absolute and for a period of two to four weeks in the average attack. It is specially important in patients who have circulatory disturbance, paralysis, respiratory difficulty or vomiting. When the patient is allowed to sit up, the effect on the pulse should be noted and if irregularity or marked change in rate appears further rest is indicated. Special emphasis should be placed on the need of prolonged rest if there is circulatory disturbance. Sudden death may follow slight exertion. Small children may require constant watching.

(c) LOCAL TREATMENT.—In this especial care should be taken to avoid mechanical injury to the tissues. Since the introduction of antitoxin, local treatment is much less important and many patients do perfectly well with little or none. As a rule there is no advantage in struggling with a child to carry out local treatment. If it is employed the frequency should be determined by the results. In some patients it gives comfort.

Boracic acid solutions, peroxide of hydrogen, Dobell's solution, and bichloride of mercury (1-2000) may be employed in the form of sprays, but in many cases the use of irrigations is the most satisfactory. This should always be done very gently with the patient lying on the side. Either a saline solution or a 2 per cent. boric acid solution is satisfactory.

Nasal diphtheria requires prompt and thorough disinfection of the passages. Salt solution, saturated boric acid or bichloride of mercury (1-5000) may be used. To be effectual the injection must be properly given. The nozzle of the syringe should be passed horizontally, not vertically; otherwise the fluid will return through the same nostril.

When the larynx is involved, a steam tent may be arranged, so that the child may breathe an atmosphere saturated with moisture. When the signs of obstruction are marked there should be no delay in the performance of intubation or tracheotomy. The choice between these must depend on the circumstances in each case. Intubation may be regarded as the operation of choice in the majority of cases. Tracheotomy is preferable in adults and may be the operation of necessity. The patient requires more skilful care after intubation than after tracheotomy. When the membrane is loose, suction with direct laryngoscopy may be used. This should be done only by one skilled in direct laryngoscopy. This procedure may have to be repeated and there should be no hesitation in doing it.

Hot applications to the neck are useful, particularly in young children, though in older children and adults the ice bag is to be preferred.

(d) GENERAL MEASURES.—Every effort should be made to nourish the patient. The food should be liquid—milk, beef juices, barley water, ice cream, albumen water, and soups. If there is difficulty in swallowing, these should be given by a tube. The patient should be encouraged to drink water freely. If there is difficulty in taking it by mouth, it should be given by the bowel or subcutaneously. The bowels should be freely opened, for which a calomel and saline purge is usually best. When the pharyngeal involvement is very great and swallowing painful, a 5 per cent. glucose solution can be given by the bowel.

For the circulation the early giving of antitoxin is the best preventive of trouble. When symptoms arise, stimulants, such as caffeine and epinephrine are indicated. Absolute rest is most important and morphia hypodermically in proper dosage for the age is useful in myocardial conditions. Digitalis should not be given if there is any indication of heart block. Saline or dextrose solution by rectum or subcutaneously is useful.

(e) ANTITOXIN TREATMENT.—As the years go on experience has shown that, thoroughly carried out, this is both safe and efficacious. It should be given as early as possible in the course of the disease as every hour's delay adds to the danger of the attack.

The principle of action depends on the circumstance that the blood-serum of an animal rendered immune, when introduced into another animal, protects it from infection with the diphtheria bacilli, and has also an important curative influence upon diphtheria, whether artificially given to animals, or spontaneously acquired by man. In the preparation of the serum a uniform standard strength is procured. The antitoxin unit is the amount of antitoxin which, injected into a guinea-pig of 250 grams in weight, neutralizes 100 times the minimum fatal dose of toxin of standard strength.

Dosage.—The ideal dose is one sufficiently large so that a second is not required. If there is any doubt as to what dose should be given choose the larger. The danger is of giving too small and not too large a dose, as the object is to neutralize the free toxin as quickly as possible. The antitoxin persists in the blood for a number of days and hence the value of a sufficient single dose. An insufficient dose at first cannot be entirely made up for by subsequent administration. In case of doubt as to the diagnosis it is wise to give antitoxin at once rather than wait for the result of cultures. The amount given should be decided by the severity of the attack, whether early or late in the course and by the seat of the local disease. When seen early and the attack is mild the smaller doses are proper. If late in the course, with severe features or in nasal or laryngeal involvement large doses should be given. In a general way the following dosage is a guide: for children up to the age of two years 2,000 to 10,000 units, from two to twelve years 3,000 to 20,000 units, and above twelve years 5,000 to 50,000 units. If a sufficient amount has been given, a second dose will not be required, but repeated doses should be given if indicated by lack of improvement or advance in the symptoms.

Administration.—Antitoxin should be given intramuscularly or intravenously. An intramuscular injection is absorbed about three times as rapidly as a subcutaneous one, and when given intravenously the whole amount is immediately available. The last is advisable in severe cases. The serum should be strongly potent, not show turbidity, warmed to body temperature and given at the rate of 1 c. c. per minute. The usual care should be taken with the needle and skin.

Favorable effects are seen in the improvement in both the local and general condition. The swelling of the fauces subsides, the membrane begins to disappear, the temperature falls, and the pulse becomes slower.

Untoward Effects.—"Serum Disease."—This may appear in any normal individual and is due to the serum and not to the antitoxin. Following the

injection after a varying interval, which varies from one to eighteen days, but is usually between seven and ten days, a local reaction appears which may be accompanied by general symptoms. The site of injection shows œdema, urticaria or erythema, which may become more or less general. Malaise, vomiting, fever, adenitis, albuminuria, and arthralgia may accompany this. The symptoms are usually not severe and disappear in three or four days. Calcium lactate (gr. xv, 1 gm. three times a day) may be given as a prophylactic or when the symptoms have appeared. There is another reaction which is much more serious. In individuals who have been given antitoxin previously, even at a long interval—who have been sensitized—in some who have had asthma and in some of those who are affected by the proximity of horses, an acute dangerous condition may be caused by the injection of serum—anaphylaxis. This comes on very suddenly and with acute symptoms, among which are extreme distress, dyspnoea, cyanosis, œdema, collapse, respiratory failure and convulsions; death may follow rapidly. Fortunately this occurs rarely, but its possibility should be kept in mind, and before giving antitoxin the patient should be asked as to a history of asthma, an idiosyncrasy to horses and previous administration of antitoxin. This must be kept in mind in the case of patients who have a relapse, as if seven days have elapsed since the first dose the patient may be sensitized. If there is any reason to suspect the possibility of a reaction, the patient should be tested by the administration of two or three drops of antitoxin, which will not give a dangerous reaction. If he is susceptible a reaction usually occurs in an hour, but it is safer to wait three hours. The intradermic injection of 0.2 c. c. of horse serum (1 to 10 dilution) or 1 c. c. of antitoxin solution in a strength of 1 to 100 of salt solution produces an urticarial wheal in a few minutes in a sensitive individual. If the patients are sensitive and the need of antitoxin is great, small doses (0.1 to 0.2 c. c. intramuscularly) should be given every 15 or 20 minutes. In the absence of reaction it is safe to give the usual dose, for a sensitized individual, after receiving a small dose, is refractory to larger doses some hours later. Children seem to be much less liable to sensitization than adults. If anaphylaxis should occur, morphia (gr. $\frac{1}{4}$, 0.016 gm.) and atropine (gr. $\frac{1}{100}$, 0.0006 gm.) hypodermically should be given at once followed by epinephrine (1 c. c. of a 1-1000 solution). Artificial respiration should be done if there is respiratory failure.

Results.—Of 183,256 cases treated in 150 cities previous to the serum period, the mortality was 38.4 per cent. Since the introduction of serum among 132,548 cases, there was a mortality of 14.6 per cent. Leaving out those not treated by serum, the mortality was 9.8 per cent. (Rosenthal). In 78 cities in the United States (nearly 34 million population) the death-rate in 1928 was 9.23 per 100,000.

Convalescence.—If there are signs of cardiac disturbance, the patient should be kept absolutely at rest. Nourishment should be given freely, strychnine administered in full doses, and iron with arsenic if there is anæmia. With the post-diphtheritic paralysis the patients should be kept in bed, fed liberally and given strychnine hypodermically. Antitoxin may be given. In chronic forms with muscular wasting, electricity and massage should be used. The patient should not be discharged from quarantine until two successive cultures from the throat and nose, two days apart, have been negative.

VII. SCARLET FEVER

Definition.—An infectious disease, the infection being local in the nasopharynx, caused by certain specific strains of hæmolytic streptococci. A soluble toxin is produced which is absorbed, causing the general and special features of the disease. There may be a secondary systemic streptococcal infection. The disease is like diphtheria in that there is a local lesion from which toxins are absorbed. The organism is the *Streptococcus scarlatinae*.

History.—In the sixteenth century Ingrassias of Naples and Coyttarus of Poitiers recognized the disease; but Sydenham in 1675 gave a full account of it under the name febris scarlatina. The isolation of the strains of streptococci, the production of scarlet fever experimentally in human subjects and the preparation of an antitoxin (by injection of the toxin into the horse) by G. F. and G. H. Dick are outstanding achievements. Dochez and his co-workers did important work in the study of the strains of organisms. They produced an antitoxin by immunizing the horse with the organisms.

Etiology.—No acute infection varies so greatly in the intensity of the outbreaks, a point to which both Sydenham and Bretonneau called attention. In some years it is mild; in others, with equally widespread epidemics, it is fearfully malignant. It is widespread, occurring in nearly all parts of the globe and attacking all races. Sporadic cases occur from time to time. The epidemics are most intense in the autumn and winter. There is an extraordinary variability in the severity of the outbreaks, which on the whole appear to be lessening in severity; in Boston from 1894 to 1903 the ratio of cases per ten thousand ranged from 45.80 to 16.18, and the mortality from 3.94 to 0.60. In England and Wales the disease is declining. In 1883 there were over 12,000 deaths; in 1903, 4,158; in 1909, 3,215, and in 1928, 580 deaths. Newsholme attributes this in part to the general improvement in sanitation, to hospital isolation, and in part to the decline in the severity of the disease.

Seibert's studies in New York show that the disease increases steadily from week to week until the middle of May; the frequency diminishes gradually until the end of June, and increases through October, November, and December. He associates the drop in July, August, and September with the closure of the schools and less daily congregation of children in small areas—schools and playgrounds—for so many hours each day.

AGE is the most important predisposing factor; 90 per cent. of the fatal cases are under the tenth year. Sucklings are rarely attacked. The general liability to the disease is less widespread than in measles. Many escape in childhood; others escape until adult life; some never take it.

FAMILY SUSCEPTIBILITY may be illustrated by the death in rapid succession of four or five members. Individual resistance is common, and many physicians constantly exposed escape. An attack as a rule confers subsequent immunity. In rare instances there have been one or even two recurrences.

IMMUNITY.—Most new-born children are immune, this being acquired from the mother, as in diphtheria. Many children lose this immunity and become susceptible. This may be determined by the intracutaneous injection of 0.2 c. c. of a 1-1000 dilution of the toxin—Dick test. With a positive reaction, signs appear in six hours, reaching a maximum in from eighteen to thirty-

six hours. The local reaction rapidly subsides and rarely persists more than forty-eight hours. In patients who are convalescent from scarlet fever the reaction is negative or only slightly positive. The production of active immunity is possible by the injection of the toxin in proper amounts. The serum from a convalescent scarlet fever patient and the antitoxin produce a passive immunity.

INFECTIVITY.—The source of infection is often not discovered in a given case. The organisms are given off with the secretions of the nose and throat and in the discharge from an otitis media. *Carriers* are important, especially those with nasal or ear discharges. The mild angina of ambulatory cases may convey the disease, and in this way it is spread in schools, and the "return cases" may find in this way their explanation. The intractable character of the nasal discharge after scarlet fever is well recognized and this secretion is highly infectious. Direct contact is probably important but the organism can persist for a long time in garments, etc.

The disease may be conveyed by *milk*. Of 99 epidemics studied by Kober the disease prevailed in 68 either at the dairy or the milk farm. There appear to be two groups of cases: first, genuine scarlet fever, in which the infection is conveyed through the milk having come in contact with infected persons; and, secondly, outbreaks of an infection resembling scarlet fever, due to disease of the udder of the cows.

By **SURGICAL SCARLATINA**, first brought to attention by Sir James Paget in 1864, is understood an erythematous eruption following an operation or occurring during septic infection. It differs from scarlet fever in the large number of adults attacked, the shorter incubation, the mildness of the throat symptoms, the starting of the eruption at the wound, and the precocious desquamation. Alice Hamilton, after analyzing 174 reported cases, concludes that the eruption is most frequently due to septic infection and in cases in which the disease was undoubtedly scarlet fever it is probable that the relation between the wound and the scarlet fever was coincidence. Allergy may be a factor, the sensitization occurring early in life.

Organism.—The association of hæmolytic streptococci with scarlet fever has long been recognized but the etiological relationship has been in doubt. Various types of hæmolytic streptococci have been differentiated and it has been shown that the hæmolytic streptococcus found in the throats of scarlet fever patients is a specific one. Dochez and his co-workers isolated this specific streptococcus from a wound and an infected burn in scarlet fever, from the lochial discharge in puerperal scarlet fever and from both the patients and infected milk in a milk-borne epidemic of scarlet fever. G. F. and G. H. Dick produced scarlet fever experimentally in human subjects by two types of hæmolytic streptococci which do and do not ferment mannite.

Morbid Anatomy.—Except in the hæmorrhagic form, the skin after death shows no traces of the rash. There are no specific lesions. Those in the internal organs are due partly to the fever and partly to infection with pus-organisms. The anatomical changes in the throat are those of simple inflammation, follicular tonsillitis, and, in extreme grades, of diphtheroid angina. In severe cases there are intense lymphadenitis and inflammatory œdema of the tissues of the neck, which may go on to suppuration, or even to gangrene. The lymph glands and the lymphoid tissue may show hyper-

plasia and the spleen, liver, and other organs may be the seat of widespread focal necroses. Endocarditis and pericarditis are not infrequent. Myocardial changes are less common. The renal changes will be considered with the diseases of the kidney. Affections of the respiratory organs are not frequent. When death results from the pseudo-membranous angina, broncho-pneumonia is not uncommon. Cerebro-spinal changes are rare.

Symptoms.—INCUBATION.—"From one to seven days, oftenest two to four." McCollom considered the usual period to be ten to fourteen days.

INVASION.—The onset is as a rule sudden. It may be preceded by a slight, scarcely noticeable, indisposition. An actual chill is rare. Vomiting is one of the most constant initial symptoms; convulsions are common. The fever is intense; rising rapidly, it may on the first day reach 104° or even 105° . The pulse rate is usually high. The skin is unusually dry and to the touch gives a sensation of very pungent heat. The tongue is furred, cough and catarrhal symptoms are uncommon. The face is often flushed and the patient has the objective features of an acute fever. There is frequently marked dryness and pain in the throat with redness of the pharynx and soft palate. The uvula may be red and oedematous. The injection of the fauces and tonsils may be very intense and exudate may form. The paratonsillar lymph-nodes at the angles of the jaws may be enlarged and tender.

ERUPTION.—Usually on the second day, in some instances within the first twenty-four hours, the rash appears in the form of scattered red points on a deep subcuticular flush; at first on the neck and chest, and spreading so rapidly that by the evening of the second day it may have invaded the entire skin. After persisting for two or three days it gradually fades. At its height the rash has a vivid scarlet hue, quite distinctive and unlike that seen in any other eruptive disease. It is an intense hyperæmia, and the anæmia produced by pressure instantly disappears. There may be fine punctiform hæmorrhages, which do not disappear on pressure. The relative prominence of the punctate and erythematous elements gives different appearances. In some cases the rash does not become uniform but remains patchy, and intervals of normal skin separate large hyperæmic areas. Tiny papular elevations may sometimes be seen, but they are not so common as in measles. With each day the rash becomes of a darker color, and there may be in parts even a bluish-red shade. Smooth at the beginning, the skin gradually becomes rougher, and to the touch feels like "goose skin." At the height of the eruption sudaminal vesicles may develop, the fluid of which may become turbid. The entire skin may at the same time be covered with small yellow vesicles on a deep red background—*scarlatina miliaris*. McCollom laid stress upon a punctate eruption in the arm-pits, groins, and on the roof of the mouth as proof of scarlet fever. There is special involvement of the flexor surfaces of the joints. Marked transverse lines at the bend of the elbow may occur early. Occasionally there are *petechiæ*, which in the malignant type of the disease become widespread and large. Small skin hæmorrhages are not uncommon, and may occur into the skin at the elbow after constriction of the upper arm (Leeds-Rumpel phenomenon).

The eruption does not always appear upon the face. Circumoral pallor is often marked. There may be a good deal of swelling of the skin, which feels uncomfortable and tense. The itching is variable; not as a rule intense at

the height of the eruption. The rash may be transitory, lasting only a few hours, and rarely persists longer than a week. The tongue at first is red at the tip and edges, furred in the centre; and through the white fur are often seen the swollen red papillæ, which give the so-called "strawberry" appearance to the tongue, particularly if the child puts out the tip of the tongue between the lips. In a few days the "fur" desquamates and leaves the surface red and rough, and it is this condition which some writers call the "strawberry," or, better, the "raspberry" tongue. Enlargement of the papillæ was the only constant sign in 1,000 cases (McCollom). The breath often has a very heavy, sweet odor.

The pharyngeal features are: (1) Slight redness, with swelling of the pillars of the fauces and of the tonsils. (2) A more intense grade of swelling and infiltration of these parts with a follicular tonsillitis. 3. Diphtheroid

CHART III.—SCARLET FEVER.

angina with intense inflammation of all the pharyngeal structures, swelling of the glands below the jaw, and in very severe cases a thick brawny induration of all the tissues of the neck.

The fever, which sets in with such suddenness and intensity, may reach 105° or even 106° F. It persists with slight morning remissions, gradually declining with the disappearance of the rash. In mild cases the temperature may not reach 103° F.; on the other hand, in very severe cases there may be hyperpyrexia, 108° F., or before death even 109° F.

The pulse ranges from 120 to 150; in severe cases with very high fever from 190 to 200. The respirations show an increase proportionate to the intensity of the fever. A polymorphonuclear leucocytosis (15,000-30,000) is usually present and inclusion bodies may be seen in the leucocytes. The gastro-intestinal symptoms are not marked after the initial vomiting, and food is usually well taken. In some instances there are abdominal pains. The edge of the spleen may be palpable. The liver is not often enlarged. The cervical, axillary and inguinal lymph nodes are usually enlarged. With the initial fever nervous symptoms are present in a majority of the cases; but as the rash comes out the headache and the slight delirium disappear. The urine has the ordinary febrile characters, being scanty and high colored. Slight albuminuria is

common during the stage of eruption. Careful examination of the urine should be made every day. There is no cause for alarm in the trace of albumin which is so often present, not even if associated with a few casts.

DESQUAMATION.—With the disappearance of the rash and the fever the skin looks somewhat stained, is dry, a little rough, and gradually the upper layer of the cuticle begins to separate. The process usually begins about the neck and chest, and flakes are gradually detached. Desquamation often begins over the papillæ and spreads in a ring shape. Peeling along the edges of the nails is characteristic and of value in late diagnosis. The degree and character of the desquamation bear some relation to the intensity of the eruption. When the latter has been very vivid and of long standing large flakes may be thrown off. In rare instances the hair and even the nails have been shed. There are cases in which the desquamation is prolonged even to the seventh or eighth week. The average time is from ten to fifteen or even twenty days.

Varieties of Scarlet Fever.—**MILD AND ABORTIVE FORMS.**—In cases of exceptional mildness the rash may be scarcely perceptible. During epidemics, when several children of a household are affected, one child has a sore throat and the “strawberry tongue,” but the rash does not appear. In school epidemics many patients may be without the rash. Desquamation, however, may follow, and in these very mild forms nephritis may occur.

MALIGNANT SCARLET FEVER.—*Fulminant Toxic Variety.*—With all the characteristics of an acute intoxication, the patient is overwhelmed by the intensity of the poison and may die within twenty-four or thirty-six hours. The disease sets in with great severity—high fever, extreme restlessness, headache, and delirium. The temperature may rise to 107° or 108°, or even higher. Convulsions may occur and the initial delirium rapidly gives place to coma. The dyspnœa may be urgent; the pulse is rapid and feeble.

HÆMORRHAGIC FORM.—Hæmorrhages occur into the skin, and there are hæmaturia and epistaxis. In the erythematous rash scattered petechiæ appear, which gradually become more extensive, and ultimately the skin may be universally involved. Death may take place on the second or third day. While this form is perhaps more common in enfeebled children, it may attack adults apparently in full health.

SEPTIC FORM.—The throat symptoms appear early and progress rapidly; the fauces and tonsils swell and are covered with a thick membranous exudate, which may extend to the posterior wall of the pharynx, forward into the mouth, and upward into the nostrils. The glands of the neck rapidly enlarge. Necrosis occurs in the tissues of the throat, the fetor is extreme, the constitutional disturbance profound, and the child dies with the clinical picture of a malignant diphtheria. Occasionally the membrane extends into the trachea and the bronchi. The Eustachian tubes and the middle ear are usually involved. When death does not take place rapidly from toxæmia there may be extensive abscess formation in the tissues of the neck with sloughing. In the separation of deep sloughs about the tonsils the carotid artery may be opened, causing fatal hæmorrhage.

SEPTICÆMIC FORM.—In this there is a marked secondary infection and death occurs in the second or third week from severe toxæmia.

Complications and Sequelæ.—**ALBUMINURIA.**—At the height of the fever there is often a slight trace of albumin in the urine, which is not of special

significance. In a majority of cases the kidneys escape without greater damage than occurs in other acute febrile affections.

NEPHRITIS is most common in the second or third week and may follow a very mild attack. It may be delayed until the third or fourth week. As a rule, the earlier it occurs the more severe the attack. It occurs in from 10 to 20 per cent. of the cases. Watch should be kept for decrease in the amount of urine and the presence of blood and albumen. Three grades of cases may be recognized:

(1) Acute hæmorrhagic nephritis. There may be suppression of urine or only a small quantity of bloody fluid laden with albumin and tube casts. Vomiting is constant, there are convulsions, and the child dies with the symptoms of acute uræmia. In severe epidemics an acute, rapidly fatal, nephritis due to scarlet fever may occur without an exanthem.

(2) Less severe cases without serious acute symptoms. There is œdema of the eyelids, with slight œdema of the feet; the urine is diminished in quantity, smoky, and contains albumin and casts. The kidney symptoms then dominate the entire case, the dropsy persists, and there may be effusion into the serous sacs. The condition may become chronic, or the patient succumbs to uræmia. Fortunately, in a majority of the cases recovery takes place.

(3) Cases so mild that they can scarcely be termed nephritis. The urine contains albumin and a few casts, but rarely blood. The œdema is slight or transient, and the convalescence is scarcely interrupted. Occasionally serious symptoms supervene. Edema of the glottis may prove rapidly fatal, and in one case the child died of acute effusion into the pleural sacs.

In other cases the œdema disappears and the child improves, though he remains pale, and a slight amount of albumin persists in the urine for months or even for years. Recovery may take place or a chronic nephritis may follow. Occasionally œdema occurs without albuminuria or signs of nephritis. Possibly it may be due to the anæmia; but there are instances in which marked changes have been found in the kidney after death, when the urine did not show the features characteristic of nephritis.

ARTHRITIS.—There are two forms: first, a severe pyæmia, with suppuration of one or more joints—part of a widespread streptococcus infection. This is an extremely serious and fatal form. Secondly, scarlatinal arthritis, analogous to that in other infections. It occurs in the second or third week; many joints are attacked, particularly the small joints of the hands. The heart may be involved. Chorea, subcutaneous nodules, purpura, and pleurisy may be complications. The outlook is usually good.

CARDIAC COMPLICATIONS.—In the severe septic cases a malignant endocarditis, sometimes with purulent pericarditis, closes the scene. Simple endocarditis is not uncommon. It may not be easy to say whether the apex systolic murmur, so often heard, signifies a valvular lesion. The persistence after convalescence, with signs of slight enlargement of the heart, may alone decide that the murmur indicated an organic change. As is the rule, such cases give no symptoms. Lastly, there may be a severe toxic myocarditis, sometimes leading to acute dilatation and sudden death. It is to be borne in mind that the cardiac complications of the disease are often latent.

ACUTE BRONCHITIS and BRONCHO-PNEUMONIA are not common. Empyema is an insidious and serious complication.

EAR COMPLICATIONS.—Common and serious, due to extension of the inflammation from the throat through the Eustachian tubes, they rank among the most frequent causes of deafness in children. The severe forms of membranous angina are almost always associated with otitis, which goes on to suppuration and to perforation of the drum. The process may extend to the labyrinth and rapidly produce deafness. In other instances there is suppuration in the mastoid cells. In the necrosis which follows the middle-ear disease the facial nerve may be involved and paralysis follow. Later, still more serious complications may follow, such as thrombosis of the lateral sinus, meningitis, or abscess of the brain. *Sinusitis* is not infrequent.

ADENITIS.—In comparatively mild cases the submaxillary lymph-glands may be swollen. In severer cases the swelling of the neck becomes extreme and extends beyond the limits of the glands. Acute phlegmonous inflammations may occur, leading to widespread destruction, in which vessels may be eroded and fatal hæmorrhage ensue. The suppurative processes may also involve the retro-pharyngeal tissues.

The swelling of the lymph-glands usually subsides, and within a few weeks even the most extensive enlargement gradually disappears. There are rare cases in which the lymphadenitis becomes chronic, and the neck remains with a glandular collar which almost obliterates its outline and proves intractable to all treatment.

NERVOUS COMPLICATIONS.—Chorea occasionally complicates the arthritis and endocarditis. Sudden convulsions followed by hemiplegia may occur. In 7 of a series of 120 cases of infantile hemiplegia the onset was during scarlet fever. Progressive paralysis of the limbs with wasting may present the features of a subacute ascending spinal paralysis. Thrombosis of the cerebral veins may occur. Mental symptoms, mania, and melancholia have been described. Encephalitis is rare and also meningitis which may develop late. Vagotonia may be marked in convalescence.

Other complications and sequæ are œdema of the eyelids, without nephritis, symmetrical gangrene, enteritis, noma, and perforation of the soft palate. Rhinitis is comparatively common. Paronychia may occur.

The fever may persist for several weeks after the disappearance of the rash, and the child may remain in a septic state. This is usually the result of some chronic suppurative process about the throat or the nose, occasionally the result of a chronic adenitis, but in a few cases nothing whatever can be found to account for the fever.

RELAPSE was noted in 7 per cent. of 12,000 (Caiger), in 1 per cent. of 1,520 (Newsholme), and in 3 per cent. of 5,000 cases (McCollom).

COEXISTENCE OF OTHER DISEASES.—Of 48,366 cases of scarlet fever in the Metropolitan Asylum Board Hospitals complicated by some other disease, in 1,094 cases the secondary infection was diphtheria, in 899 cases chicken-pox, in 703 measles, in 404 whooping-cough, in 55 erysipelas, in 11 typhoid fever, and in 1 typhus fever (F. F. Caiger). Farnarier (1904) found only 39 undoubted cases of the coexistence of typhoid and scarlet fever.

Diagnosis.—This is not difficult in typical attacks when the patient is seen early but in mild cases with a transitory rash or after the acute features are over, it may be very difficult. The following are the most common conditions with which scarlet fever may be confounded:

ACUTE EXFOLIATING DERMATITIS.—This simulates scarlet fever very closely. It has a sudden onset, with fever. The eruption spreads rapidly, is uniform, and after persisting for five or six days begins to fade. Even before it has entirely gone desquamation usually begins, sometimes leaving erythematous skin. Some cases cannot be distinguished from scarlet fever in the stage of eruption. The throat symptoms are usually absent, and the tongue rarely shows the changes which are so marked in scarlet fever. In the desquamation of this affection the hair and nails are commonly affected. It is, too, a disease liable to recur. Some of the instances of second and third attacks of scarlet fever have been cases of this form of dermatitis.

MEASLES is distinguished by the longer period of invasion, the characteristic prodromes, and the later appearance of the rash. The greater intensity of the measly rash upon the face, the more papular character and the irregular crescentic distribution are distinguishing features in a majority of cases. Other points are the absence in measles of the sore throat, the peculiar character of the desquamation, the absence of leucocytosis, and the presence of Koplik's sign.

RUBEOLA.—The rash is sometimes strikingly like that of scarlet fever. In cases of doubt the mild general symptoms are our best guide. The catarrhal symptoms and adenitis are helpful.

SEPTICÆMIA.—The so-called puerperal or surgical scarlatina shows an eruption which may be identical in appearance with that of scarlet fever.

DIPHTHERIA.—The practitioner may be in doubt whether he is dealing with scarlet fever with intense membranous angina, a true diphtheria with an erythematous rash, or coexisting scarlet fever and diphtheria. A rash in diphtheria is, after all, not common, is limited usually to the trunk, is not so persistent, and is generally darker than the scarlatinal rash. Cultures are important in doubtful cases. Scarlet fever and diphtheria may coexist, but in a case presenting widespread erythema and extensive membrane with diphtheria bacilli, only the specific skin reaction may determine if scarlet fever is present. The streptococcus angina is not so apt to extend to the larynx, nor are recurrences so common; but general infection may occur, the membrane may spread downward with great rapidity, and all the nervous sequelæ of diphtheria may follow a streptococcus infection.

FOOD, SERUM AND DRUG RASHES.—The history and general features are important, while the rashes are partial, and seldom more than a transient hyperæmia. Occasionally they are diffuse and intense, and in such cases very deceptive. They are not associated with the characteristic symptoms of invasion and there is no fever. They are most apt to follow the use of belladonna, quinine, pheno-barbital and iodide. The antitoxin erythema may cause doubt, particularly in hospitals for infectious diseases.

Specific Reaction.—The intracutaneous injection of serum from a person immune to or convalescent from scarlet fever into a patient with scarlet fever produces a local area of blanching which persists until the rash has faded. These phenomena suggest the neutralization of a toxin in the tissues. A positive reaction with the Dick test early in convalescence from a doubtful attack is against scarlet fever as also a negative reaction early in an illness.

How Long Is a Child Infective?—Usually in six weeks the danger is thought to be over, but the occurrence of so-called "return cases" shows that

patients remain infective even at this stage. With 15,000 cases submitted to an average period of isolation of forty-nine days or under, the percentage of return cases was 1.86; with an average period of fifty to fifty-six days the percentage was 1.12; where the isolation extended to between fifty-seven and sixty-five days the percentage of return cases was 1 (Neech). This author suggests eight weeks as a minimum and thirteen weeks as a maximum. Special care should be taken of patients with rhinorrhœa, otorrhœa and throat trouble, as the secretions from these parts are often infective.

Prognosis.—The death-rate has been falling of late years. Epidemics differ remarkably in severity and the mortality is extremely variable. Among the better classes the death-rate is much lower than in hospital practice. There are physicians who have treated consecutively a hundred or more patients without a death. On the other hand, in hospitals and among the poorer classes the death-rate may be considerable, ranging from 5 to 10 per cent. in mild epidemics to 20 or 30 per cent. in the very severe. In 1,000 cases reported from the Boston City Hospital by McCollom the death-rate was 9.8 per cent. There is a curious variability in the local mortality from this disease. In England, for example, in some years, certain counties enjoy almost immunity from fatal scarlet fever. The younger the child the greater the danger. In infants under one year the death-rate is very high. The great proportion of fatal cases occurs in children under six years of age. The unfavorable symptoms are high fever, severe toxæmia, broncho-pneumonia, the occurrence of hæmorrhages (cutaneous or visceral), intense throat infection, cervical cellulitis, and signs of laryngeal obstruction. Nephritis is always serious, and setting in with suppression of urine may quickly prove fatal; a large majority of the cases recover.

Prophylaxis.—Meanwhile, a rigid system of school inspection, and general recognition of the importance of latent cases and the persistence of infection in the secretions of the nose and throat will aid. The attendant in a case of scarlet fever should take the most careful precautions against the conveyance of the disease, wearing a gown and thoroughly washing the hands and face after leaving the room. To the busy practitioner the minutiae of proper disinfection are irksome, but it is his duty to carry out the most rigid care possible, and intelligent people expect it. The duration of quarantine varies with the attack: six to eight weeks is the average period. Patients with discharge from the ear or nose require longer isolation.

The test for susceptibility and the immunization of those found to be susceptible give the means of preventing the disease. The profession should strive to educate the public as to the wisdom of these preventive measures in scarlet fever as in diphtheria. The use of antitoxin, to produce passive immunity, is of value in susceptible persons who have been exposed to infection. Active immunization is produced by the toxin.

Treatment.—The patient may be treated at home or sent to an isolation hospital. The difficulty in *home treatment* is in securing complete isolation. The risks are well illustrated by the studies of Chapin, of Providence, who found that during eight years 26.1 per cent. of the 4,412 persons under twenty-one years of age in infected families took the disease. When practicable, it is better to send the other children out of the house. Chapin's experience on this point is most interesting. In seventeen years, from 652 families infected

with scarlet fever, 1,051 children, none of whom had had the disease, were removed. Only 5 per cent. were attacked while away from home. Nineteen who had been sent away from the infected houses were attacked on their return.

The patient should be isolated, in charge of a competent nurse and be kept in bed for three weeks at least. The temperature of the room should be constant and the ventilation thorough. The child should wear a light flannel nightgown, and the bedclothing should not be too heavy. The mouth should be kept clean and rinsed freely with a mild antiseptic solution. The diet should consist of milk, buttermilk, whey, and ice cream; water and fruit juices should be freely given. Cream and lactose may be added to the milk. With the fall of the temperature the diet may be increased very slowly, farinaceous food being added first, later the child may gradually return to ordinary fare. When desquamation begins the child should be thoroughly rubbed every day, or every second day, with sweet oil, or vaseline, which prevents the drying and the diffusion of the scales. An occasional warm bath may then be given. At any time during the attack the skin may be sponged with warm water. In convalescence great care should be exercised to prevent exposure to cold. It must not be forgotten that the renal complications are very apt to occur during convalescence, and after all danger is apparently past. Ordinary cases may be given a simple fever mixture, and during convalescence a bitter tonic. The bowels should be carefully regulated.

When the fever is above 103° F. the extremities may be sponged with tepid water. In severe cases, with the temperature rapidly rising, this will not suffice, and more thorough measures of hydrotherapy should be practised. With pronounced delirium and nervous symptoms the wet pack should be used. When the fever is rising rapidly but the child is not delirious, he should be placed in a warm bath, the temperature of which can be gradually lowered. In giving the pack a rubber sheet and a thick layer of blankets should be spread upon a sofa or a bed, and over them a sheet wrung out of water. The naked child is laid upon it and wrapped in blankets. An intense glow of heat quickly follows the preliminary chilling, and from time to time the blankets may be unfolded and the child sprinkled with water. The good effects which follow are often striking, particularly in allaying the delirium and jactitation, and procuring quiet sleep. Parents object less, as a rule, to the warm bath gradually cooled than to any other form of hydrotherapy. The child may be removed from the warm bath, placed upon a sheet wrung out of tolerably cold water, and then folded in blankets. The ice-cap is useful and may be kept constantly applied when there is a high fever. Medicinal antipyretics are not of much service in comparison with cold water. If the child is restless or sleepless, hydrotherapy is usually effectual. If not moderate doses of bromide may be given.

The throat symptoms, if mild, do not require much treatment. If severe, the local measures mentioned under diphtheria should be used. The nose should be kept clean, for which a simple alkaline douche, given gently, is best. Cold applications to the neck are to be preferred to hot, though it is sometimes difficult to get a child to submit to them. If cervical adenitis occurs, an ice bag should be applied, and with the first signs of suppuration an incision made. In connection with the throat, the ears should be specially watched and careful disinfection of the mouth and fauces by suitable antiseptic

solutions should be practised. When the inflammation extends through the tubes to the middle ear, the practitioner should examine daily the condition of the drum, or, when available, a specialist should be called in to assist. The careful watching of this membrane day by day and early puncture when required may save the hearing. The operation may be repeated at intervals if the pain and distention return. Watch should be kept for mastoiditis.

The nephritis should be dealt with as in ordinary cases; indications for treatment will be found under the appropriate section. Many insist upon the great value of milk diet in scarlet fever as a preventive of nephritis.

Among other indications for treatment is cardiac weakness, for which digitalis, or if urgent strophanthin intramuscularly, may be given.

SERUM TREATMENT.—The use of antitoxin (3,000-12,000 units, intramuscularly, as early as possible) promises much and should be as successful as in diphtheria. The serum of convalescents taken in the fourth or fifth week has been used in doses of 50-90 c. c. intramuscularly.

VIII. THE PNEUMONIAS AND PNEUMOCOCCIC INFECTIONS

A variety of diseases are caused by the pneumococcus, among which lobar and broncho-pneumonia are the most important. Various inflammatory affections of the lungs may be caused by other organisms, but the pneumococcus plays the important rôle in the common lobar pneumonia and in the ordinary broncho-pneumonia. It may set up also many local affections and is the cause of many terminal infections in chronic diseases.

A. LOBAR PNEUMONIA

(Croupous or Fibrinous Pneumonia, Lung Fever)

Definition.—An infection usually caused by the pneumococcus, characterized by inflammation of the lungs, a toxæmia of varying intensity and a fever which terminates by crisis in about 50 per cent. of the cases.

History.—The disease was known to Hippocrates and the old Greek physicians, by whom it was confounded with pleurisy. Among the ancients, Aretæus gave a remarkable description. "Ruddy in countenance, but especially the cheeks; the white of the eyes very bright and fatty; the point of the nose flat; the veins in the temples and neck distended; loss of appetite; pulse, at first, large, empty, very frequent, as if forcibly accelerated; heat indeed, externally, feeble, and more humid than natural, but, internally, dry and very hot, by means of which the breath is hot; there is thirst, dryness of the tongue, desire of cold air, aberration of mind; cough mostly dry, but if anything be brought up it is a frothy phlegm, or slightly tinged with bile, or with a very florid tinge of blood. The blood-stained is of all others the worst." At the end of the seventeenth and the beginning of the eighteenth century Morgagni and Valsalva made many accurate clinical and anatomical observations on the disease. Our modern knowledge dates from Laënnec (1819), whose masterly description of the physical signs and morbid anatomy left very little for subsequent observers to add or modify.

Incidence.—One of the most widespread and fatal of all acute diseases, pneumonia has become the “Captain of the Men of Death,” to use the phrase applied by John Bunyan to consumption. In England and Wales in 1928 there were 36,623 deaths from this cause. In the United States in the registration area in 1925 there were 101,637 deaths, a rate of 83.5 per 100,000; of these 56,612 were due to lobar pneumonia, 39,820 to broncho-pneumonia, and 5,205 were unclassified.

Careful studies of tropical pneumonia have been made at Panama. At the Ancon Hospital among 574 cases the mortality was 37 per cent.; among the mixed races, natives of the Isthmus, from 50 to 60 per cent. The same high death-rate prevails at the Colon Hospital. Among the natives employed in the Transvaal mines the disease was very fatal, killing a larger number than any other disease, tuberculosis coming second. It is more particularly among the natives during the first month of work in the mines, 443 per thousand of all deaths during this period. There is a marked decline in succeeding periods of six months—from 16 per thousand in the first six months to 9.24 per thousand in the second six months, and 5.5 per thousand in the third six months. The case mortality is not extraordinarily high. In Johannesburg the deaths among the colored people fell from 1,196 in 1912-'13 (a rate of 10.79 per 1,000 population) to 325 in 1913-'14 (a rate of 3.09 per 1,000) coincident with improvement in the sanitary condition of the dwellings.

Etiology.—AGE.—To the sixth year the predisposition to pneumonia is marked; it diminishes to the fifteenth year, but then for each subsequent decade it increases. For children Holt's statistics of 500 cases give: First year, 15 per cent.; from the second to the sixth year, 62 per cent.; from the seventh to the eleventh year, 21 per cent.; from the twelfth to the fourteenth year, 2 per cent. Lobar pneumonia has been met with in the new-born. The relation to age is well shown in the U. S. Census Report for 1900. The death-rate in persons from fifteen to forty-five years was 100.05 per 100,000 of population; from forty-five to sixty-five years it was 263.12; and in persons sixty-five years of age and over it was 733.77. Pneumonia may well be called the friend of the aged. Taken off by it in an acute, short, not often painful illness, the old escape those “cold gradations of decay” that make the last stage of all so distressing.

SEX.—Males are more frequently affected than females—533 to 125 in the Johns Hopkins Hospital series.

RACE.—In the United States pneumonia is more fatal in negroes than among the whites. It is rare among the Chinese.

SOCIAL CONDITION.—The disease is more common in the cities. Overcrowding probably is a factor. Individuals who are much exposed to hardship and cold are particularly liable to the disease. Newcomers and immigrants are stated to be less susceptible than native inhabitants.

PERSONAL CONDITION.—Debilitating causes of all sorts render individuals more susceptible. Alcoholism is perhaps the most potent predisposing factor. Robust, healthy men are, however, often attacked.

PREVIOUS ATTACK.—No other acute disease recurs in the same individual with such frequency. Instances are on record of individuals who have had ten or more attacks. The percentage of recurrences has been placed as high

as 50. Netter gives it as 31, and he collected the statistics of eleven observers who place the percentage at 26.8.

TRAUMA.—*Contusion-Pneumonia.*—Pneumonia may follow directly upon injury, particularly of the chest, without necessarily any lesion of the lung. Collapse of the lung may be mistaken for it. Stern describes three clinical varieties: first, the ordinary lobar pneumonia following a contusion of the chest wall; secondly, atypical cases, with slight fever and not very characteristic physical signs; thirdly, cases with the physical signs and features of bronchopneumonia. The last two varieties have a favorable prognosis. According to Ballard, workers in certain phosphate factories, where they breathe a very dusty atmosphere, are particularly prone to pneumonia.

Cold has been for years regarded as an important etiological factor. The frequent occurrence of an initial chill has been one reason for this widespread belief. As to the close association of pneumonia with exposure there can be no question. We see the disease occur promptly after a wetting or a chilling due to some unusual exposure, or come on after an ordinary catarrh of one or two days' duration. Cold is regarded simply as a factor in lowering the resistance of the bronchial and pulmonary tissues.

CLIMATE AND SEASON.—Climate does not appear to have very much influence, as pneumonia prevails equally in hot and cold countries. It is stated to be more prevalent in the southern than in the northern states, but the Census Reports show little difference in the various state groups. The disease is less prevalent in England than in the United States, where the dry, overheated air of the houses favors catarrhal processes in the air passages. Much more important is the influence of *season*. Statistics are almost unanimous in placing the highest incidence in the winter and spring months. The statistics from many localities give the highest percentage in January, February and March.

Bacteriology.—(a) **PNEUMOCOCCUS OR DIPLOCOCCUS PNEUMONIAE.**—In September, 1880, Sternberg inoculated rabbits with his own saliva and isolated a micrococcus. The publication was not made until April, 1881. Pasteur discovered the same organism in the saliva of a child dead of hydrophobia in December, 1880, and the priority of the discovery belongs to him, as his publication is dated January, 1881. There was, however, no suspicion that this organism was concerned in the etiology of lobar pneumonia, and it was not really until April, 1884, that Fraenkel determined that the organism found by Sternberg and Pasteur in the saliva, and known as the "coccus of sputum septicæmia, was the most frequent germ in pneumonia.

The organism is a somewhat elliptical, lance-shaped coccus, usually occurring in pairs; hence the term diplococcus. There are a number of groups based upon well defined immunological differences. Types I and II each comprise about one-third of the cases with a mortality of 25-30 per cent. Type III comprises 10-15 per cent. with a mortality about 50 per cent. and Type IV, the remainder with a mortality about 12 per cent. The relative figures vary in different years. Young persons seem especially susceptible to Type I and the elderly to Type III infections. Organisms of Type IV are the commonest forms in the mouths of healthy individuals. A fifth well-marked strain has been determined in South Africa by Lister.

Distribution in the Body.—In the bronchial secretions and in the affected

lung the pneumococcus is readily demonstrated in smears, and in the latter in sections. It is possible to isolate the pneumococcus from the blood in about one-third of all cases of lobar pneumonia.

(1) *In the Mouth.*—The pneumococcus is present in the mouths of a large proportion of healthy individuals (Types III and IV), various observers giving 80 to 90 per cent. Types I and II are not often found in the mouths of healthy individuals and infection due to these is acquired from without. The virulence is not always uniform and may increase during the winter months. Some persons always harbor a virulent variety. Buerger studied the communicability of the organism from one person to another and found that normal individuals—i. e., persons in whose mouths the pneumococcus was proved to be absent—acquired the organisms by association with cases of pneumonia, or with healthy persons in whose saliva pneumococci were present.

(2) *Outside the Body.*—The viability of the pneumococcus is not great. It has been found occasionally in the dust and sweepings of rooms, but Wood has shown (New York Commission Report) that the germs exposed to sunlight die in a very short time—an hour and a half being the limit. In moist sputum kept in a dark room the germs lived ten days, and in a badly ventilated room in which a person with pneumonia coughed, the germs suspended in the air retained their vitality for several hours.

(b) *BACILLUS PNEUMONIÆ OF FRIEDLÄNDER.*—This is a larger organism than the pneumococcus, and appears in the form of plump, short rods. It shows a capsule, but presents marked differences from the pneumococcus. It may cause broncho-pneumonia and other affections, and is not a cause of genuine lobar pneumonia. The exudate caused by this bacillus is usually more viscid and poorer in fibrin than that in diplococcus pneumonia.

(c) *OTHER ORGANISMS.*—Various bacteria may be associated with the pneumococcus in lobar pneumonia, the most common of these being streptococci, staphylococci, and Friedländer's pneumo-bacillus; but while these latter may cause broncho-pneumonia, they have not been satisfactorily demonstrated to be other than secondary invaders in lobar pneumonia. Likewise the pneumonias caused by *B. typhosus*, *B. diphtheria*, and the influenza bacillus are not to be identified with true lobar pneumonia.

Clinically, the infectious nature of pneumonia was recognized long before we knew anything of the pneumococcus. It may occur in endemic form, localized in certain houses, in barracks, jails, and schools. As many as ten occupants of one house have been attacked. Several members of a family may be attacked consecutively with a most malignant type of pneumonia. The disease may assume epidemic proportions. In the Middlesborough epidemic, studied by Ballard, 682 persons were attacked, with a mortality of 21 per cent. During some years pneumonia is so prevalent that it is practically pandemic. Direct infection is suggested by the fact that a patient in the next bed to one with pneumonia may take the disease, or 2 or 3 cases may follow in rapid succession in a ward. It is very exceptional, however, for nurses or doctors to be attacked.

Infection and Immunity.—Under ordinary conditions practically everyone harbors some type of pneumococcus and for periods one may have predominantly one fixed type. There are carriers of pathogenic varieties of the pneumococcus who do not have pneumonia but who distribute the organisms.

It is probable that pneumonia results when infection with a pathogenic strain of the pneumococcus coincides with lowered resistance in the individual. It is usually impossible to trace the source of infection.

There are three phases in the infection—a period of incubation and onset, the clinical manifestations, and the immunization characterized by the crisis. The attack is usually attributed to lowered general resistance, but experimentally there is basis for the view that local conditions in the lung, such as the catarrhal processes, favor the development of pneumococci. Changes leading to lobar consolidation may be regarded as local defensive reactions. The explosive onset bears a certain resemblance to the anaphylactic reaction. The attack begins abruptly in about 50 per cent. of the cases; in the other 50 per cent. it is secondary to a preceding respiratory tract infection. The process apparently begins about the hilus in many cases.

The clinical features are a toxæmia, plus disturbances of respiratory and circulatory functions. The intoxication bears no proportion to the local lesion. There are profound general infections with little or no pulmonary involvement. Some of the most toxic cases, particularly in the aged, have very slight lesions, while a lung may be solid and the patient show no signs of poisoning. The nature of the toxæmia is unknown or, possibly due to absorption of the products of the local exudate, which does not seem likely, as the symptoms abate after crisis when this absorption is most active. To regard the symptoms as due to absorption of an endotoxin is natural. Studies on the oxygen and carbon dioxide contents of the blood by Peabody show no change in the reaction of the body tissues beyond the mild grade of acidosis common in all fevers.

The explanation of the crisis is obscure. Immune bodies are not constantly increased after it, or they may not appear for several days. Upon what the neutralization of the toxins depends is doubtful.

Anoxæmia.—Oxygen deficiency is an important factor and the amount in the arterial blood may be reduced from the normal 95 per cent. to 75 per cent. This increases the dyspnœa and the heart rate and causes serious disturbance in the nervous system. It is not possible to separate accurately the features caused by anoxæmia from those due to toxæmia.

Morbid Anatomy.—Since the time of Laënnec, three stages in the inflamed lung are recognized: engorgement, red hepatization and gray hepatization.

In the stage of engorgement the lung tissue is deep red in color, firmer to the touch, and more solid, and on section the surface is bathed with blood and serum. It still crepitates, though not so distinctly as healthy lung, and excised portions float. The air cells can be dilated by insufflation from the bronchus. The capillary vessels are greatly distended, the alveolar epithelium swollen, and the air cells occupied by a variable number of blood corpuscles and detached alveolar cells. In the stage of red hepatization the lung tissue is solid, firm, and airless. If the entire lobe is involved it looks voluminous, and shows indentations of the ribs. On section, the surface is dry, reddish-brown in color, and has lost the deeply congested appearance of the first stage. One of the most remarkable features is the friability; in striking contrast to the healthy lung, which is torn with difficulty. The surface has a granular appearance due to the fibrinous plugs filling the air cells. The

distinctness of this appearance varies greatly with the size of the alveoli, which are about 0.10 mm. in diameter in the infant, 0.15 or 0.16 in the adult, and from 0.20 to 0.25 in old age. On scraping the surface with a knife a reddish viscid serum is removed, containing small granular masses. The smaller bronchi often contain fibrinous plugs. If the lung has been removed before the heart, it is not uncommon to find solid moulds of clot filling the blood-vessels. Microscopically, the air cells are seen to be occupied by coagulated fibrin in the meshes of which are red blood corpuscles, leucocytes, and alveolar epithelium. The alveolar walls are infiltrated and leucocytes are seen in the interlobular tissues. Cover-glass preparations from the exudate, and thin sections show, as a rule, the diplococci, many of which are contained within cells. Staphylococci and streptococci may be seen in some cases. In the stage of *gray hepatization* the tissue has changed from a reddish-brown to a grayish-white color. The surface is moister, the exudate obtained on scraping is more turbid, the granules in the acini are less distinct, and the lung tissue is still more friable. The air cells are densely filled with leucocytes, the fibrin network and the red blood corpuscles have largely disappeared. A more advanced condition of gray hepatization is that known as *purulent infiltration*, in which the lung tissue is softer and bathed with a purulent fluid. Small abscess cavities may form, and by their fusion larger ones, though this is a rare event in ordinary pneumonia.

RESOLUTION.—The changes in the exudate which lead to resolution are due to an autolytic digestion by proteolytic enzymes, which are present more abundantly in gray hepatization than in the preceding stage. The dissolved exudate is for the most part excreted by the kidneys. By following the nitrogen excess in the urine the progress of resolution may be followed and even an estimate formed of the amount of the exudate thus eliminated. H. W. Cook found in cases of delayed resolution that the nitrogen excess in the urine (which persisted until the lung was clear) was large, and suggests that delayed resolution may be a matter of continued exudation.

GENERAL DETAILS OF THE MORBID ANATOMY.—In 100 autopsies at the General Hospital, Montreal, in 51 cases the right lung was affected, in 32 the left, in 17 both organs. In 27 cases the entire lung, with the exception, perhaps, of a narrow margin at the apex and anterior border, was consolidated. In 34 cases, the lower lobe alone was involved; in 13 cases, the upper lobe alone. When double, the lower lobes were usually affected together, but in three instances the lower lobe of one and the upper lobe of the other were attacked. In 3 cases both upper lobes were affected. Occasionally the disease involves the greater part of both lungs. In a third of the cases, red and gray hepatization existed together. In 22 instances there was gray hepatization. As a rule the unaffected portion of the lung is congested or oedematous. When the greater portion of a lobe is attacked, the uninvolved part may be in a state of almost gelatinous oedema. The unaffected lung is usually congested, particularly at the posterior part. This may be largely due to post-mortem subsidence. The uninfamed portions are not always congested and oedematous. The upper lobe may be dry and bloodless when the lower lobe is consolidated. The average weight of a normal lung is about 600 grams, while that of an inflamed organ may be 1,500 or even 2,500 grams.

The bronchi contain, as a rule, at the time of death a frothy serous fluid,

rarely the tenacious mucus so characteristic of pneumonic sputum. The mucous membrane is usually reddened, rarely swollen. In the affected areas the smaller bronchi often contain fibrinous plugs, which may extend into the larger tubes, forming perfect casts. The bronchial glands are swollen and may even be soft and pulpy. The *pleural* surface of the inflamed lung is invariably involved when the process becomes superficial. Commonly, there is only a thin sheeting of exudate, producing slight turbidity of the membrane. The pleura was not involved in only two of the hundred instances. In some cases the fibrinous exudate may form a creamy layer an inch in thickness. A serous exudation of variable amount is not uncommon.

· LESIONS IN OTHER ORGANS.—The heart, particularly its right chamber, is distended with firm, tenacious coagula, which can be withdrawn from the vessels as dendritic moulds. In no other acute disease do we meet with coagula of such solidity. The spleen is often enlarged, though in only 35 of the 100 cases was the weight above 200 grams. The kidneys show parenchymatous swelling, turbidity of the cortex, and, in a very considerable proportion of the cases—25 per cent.—chronic interstitial changes.

Pericarditis was present in 35 of 658 cases in our series (Chatard). *Endocarditis* occurred in 16 of the 100 post mortems; in 5 of these it was of the simple character; in 11 the lesions were ulcerative. Of 209 cases of malignant endocarditis collected from the literature, 54 occurred in pneumonia. Kanthack found an antecedent pneumonia in 14.2 per cent. of cases of infective endocarditis. Of 517 fatal cases of acute endocarditis, 22.3 per cent. were in pneumonia (E. F. Wells). It is more common on the left than on the right side of the heart. Among 658 cases of pneumonia in the Johns Hopkins Hospital endocarditis occurred in 15 (Marshall). *Myocarditis* and fatty degeneration of the heart may be present in protracted cases.

Meningitis, which is not infrequent, may be associated with malignant endocarditis. It was present in 8 of the 100 autopsies. Of 20 cases of meningitis in ulcerative endocarditis 15 occurred in pneumonia.

Croupous or diphtheritic inflammation may occur in other parts. A *croupous colitis* is not very uncommon and occurred in 5 of the 100 post mortems. It is usually a thin, flaky exudation, most marked on the tops of the folds of the mucous membrane. In one case there was a patch of *croupous gastritis*. The liver shows parenchymatous changes, and often extreme engorgement of the hepatic veins. Degeneration of the muscle fibres of the diaphragm is common, probably due to anoxæmia.

Symptoms.—COURSE IN TYPICAL CASES.—We know but little of the incubation period, but it is probably very short. There are sometimes slight catarrhal symptoms for a day or two. As a rule, the disease sets in abruptly with a severe *chill*, which lasts from fifteen to thirty minutes or longer. In no acute disease is an initial chill so constant or so severe. The patient may be taken abruptly in the midst of his work or awoken out of sleep in a rigor. The temperature taken during the chill shows that the fever has already begun. If seen shortly after the onset, the patient usually has features of an acute fever, and complains of *headache* and *general pains*. Within a few hours there is *pain in the side*, often of an agonizing character; a *short, dry, painful cough begins*, and the *respirations are increased in frequency*. When seen on the second or third day, the picture in typical pneumonia is more distinct—

tive than that presented by any other acute disease. The patient lies often on the affected side; the face is flushed, particularly one or both cheeks; the breathing is hurried, accompanied often with a short expiratory grunt; the *alæ nasi* dilate with each inspiration; herpes is usually present on the lips or nose; the eyes are bright, the pupils are often unequal, the expression is anxious, and there is a frequent short cough which makes the patient wince and hold his side. The expectoration is blood-tinged and extremely tenacious. The temperature may be 104° or 105° . The pulse is full and bounding and the pulse-respiration ratio much disturbed. Examination of the lungs shows the physical signs of consolidation with blowing breathing and fine râles. After persisting for seven to ten days if a crisis occurs, with a fall in the temperature the patient passes from a condition of extreme distress and anxiety to one of comparative comfort.

SPECIAL FEATURES.—The fever rises rapidly, and the height may be 104° or 105° within twelve hours. Having reached the fastigium, it is remarkably constant. Often the two-hour temperature chart will not show more than a degree of variation for several days. In children and in cases without chill the rise is more gradual. In old persons and in drunkards the temperature range is lower than in children and in healthy individuals; one occasionally meets with an afebrile pneumonia. The degree of fever is no guide to the severity of the infection.

Pain.—There is early a sharp, agonizing pain, generally referred to the region of the nipple or lower axilla of the affected side, and much aggravated by deep inspiration and coughing. It is associated, as Aretæus remarks, with involvement of the pleura. It is absent in central pneumonia, and much less frequent in apex-pneumonia. The pain may be severe enough to require a hypodermic injection of morphia. With involvement of a lower lobe, especially in children, the pain may be altogether abdominal, suggesting some acute condition, especially appendicitis. The operation for appendicitis has been performed.

Dyspnoea is almost constant and even early in the disease the respirations may be 30 in the minute, and on the second or third day between 40 and 50. In children the respirations may be 80 or even 100. The movements are shallow, evidently restrained, and if the patient is asked to draw a deep breath he cries out with the pain. Expiration is frequently interrupted by an audible grunt. At first with the increased respiration there may be no sensation of distress. Later this may be present in a marked degree. Many factors combine to produce the shortness of breath—pain, toxæmia, fever, anoxæmia, acidosis possibly, and loss of function in a considerable area of the lung. There is more pulmonary work required and less lung to do it. Sometimes there appear to be nervous factors at work. That it does not depend upon the consolidation is shown by the fact that after the crisis, without any change in the condition of the lung, the number of respirations may drop to normal. Cyanosis of some degree is usually present and if severe it means a serious condition of anoxæmia.

Cough.—This usually comes on with the pain, and at first is dry, hard, and without any expectoration. Later it becomes very characteristic—frequent, short, restrained, and associated with great pain in the side. In old persons, in drunkards, in terminal pneumonias, and sometimes in young

children, there may be no cough. After the crisis the cough usually becomes much easier and the expectoration more easily expelled. The cough is sometimes persistent, continuous, and by far the most aggravated and distressing symptom of the disease. Paroxysms of coughing of great intensity after the crisis suggest a pleural exudate.

Sputum.—A brisk hæmoptysis may be the initial symptom. At first the sputum may be mucoid, but usually after twenty-four hours it becomes blood-tinged, viscid, and very tenacious. At first quite red from the unchanged blood, it gradually becomes rusty or of an orange yellow. The tenacious viscosity of the sputum is remarkable; it often has to be wiped from the lips of the patient. When jaundice is present it may be green or yellow. In low types of the disease the sputum may be fluid and of a dark brown color, resembling prune juice. The amount is very variable, ranging from 100 to 300 c. c. in the twenty-four hours. In 100 cases studied by Emerson, in 16 there was little or no sputum; in 32 it was typically rusty; in 33 blood-streaked; in 3 cases the sputum was very bloody. In children and old people there may be no sputum whatever. After the crisis the quantity is variable, abundant in some cases, absent in others.

Microscopically, the sputum consists of leucocytes, mucus corpuscles, red blood corpuscles in all stages of degeneration, and bronchial and alveolar epithelium. Hæmatoidin crystals are occasionally met with. The pneumococcus is usually present, and sometimes other organisms. Very interesting constituents are small cell moulds of the alveoli and fibrinous casts of the bronchioles; the latter may be plainly visible to the naked eye and sometimes may form good-sized dendritic casts. Chemically, the expectoration is particularly rich in calcium chloride.

PHYSICAL SIGNS.—*Inspection.*—The position of the patient is not constant. He usually rests more comfortably on the affected side, or he is propped up with the spine curved toward it. Orthopnoea is rare.

In a small lesion no difference may be noted between the sides; as a rule, movement is much less on the affected side, which may look larger. With involvement of a lower lobe, the apex on the same side may show greater movement. The compensatory increased movement on the sound side is sometimes very noticeable. The intercostal spaces are not usually obliterated. When the cardiac lappet of the left upper lobe is involved there may be a marked increase in the area of visible cardiac pulsation. Pulsation of the affected lung may cause a marked movement of the chest wall (Graves). Other points to be noticed are the frequency of respiration, the action of the accessory muscles, and the dilatation of the nostrils with each inspiration. Asynchronous contractions of the respiratory muscles occur in many cases. When fully developed the diaphragm and thoracic respiratory muscles contract alternately (Coleman). It is of grave significance.

Mensuration may show a definite increase in the volume of the side affected, rarely more, however, than 1 or 1½ cm.

Palpation.—The lack of expansion on the affected side is sometimes more readily perceived by touch than by sight. The pleural friction may be felt. The voice fremitus is greatly increased in comparison with the corresponding point on the healthy side. It is to be noted that if the bronchi are filled with thick secretion, or if, in what is known as massive pneumonia, they are filled

with fibrinous exudate, the tactile fremitus may be diminished. It is always well to ask the patient to cough before testing the fremitus.

Percussion.—In the stage of engorgement the note is higher pitched and may have a tympanitic quality. This can often be obtained over the lung tissue just above a consolidated area. L. A. Conner calls attention to a point which all observers must have noticed, that, when the patient is lying on his side, the percussion at the dependent base is “deeper and more resonant than that of the upper side,” which by contrast may seem abnormal, and there may even be a faint tubular element added to the vesicular breathing on the compressed side. When the lung is hepatized, the percussion note is dull, the quality varying from a note which has a certain tympanitic quality to one of absolute flatness. There is not the wooden flatness of effusion and the sense of resistance is not so great. During resolution the tympanitic quality of the percussion note usually returns. For weeks or months after convalescence there may be a higher-pitched note on the affected side. Wintrich’s change in the percussion note when the mouth is open may be present in pneumonia of the upper lobe. Occasionally there is an almost metallic quality over the consolidated area, and when this exists with a pronounced amphoric quality in the breathing the presence of a cavity may be suggested. In deep-seated pneumonias there may be no change in the percussion note for several days. *Tympany* is common in lobar pneumonia. It occurs with beginning and clearing consolidation, with consolidation over a bronchus, where air-containing lung is over consolidated lung and sometimes over an area close to consolidation.

Auscultation.—Quiet, suppressed breathing in the affected part is often a marked feature in the early stage, and is always suggestive. Only in a few cases is the breathing harsh or puerile. Very early there is heard at the end of inspiration the fine crepitant râle, a series of minute cracklings heard close to the ear, and perhaps not audible until a full breath is drawn. This is possibly a fine pleural crepitus, as J. B. Leaming maintained; it is usually believed to be produced in the air-cells and finer bronchi by the separation of the sticky exudate. In the stage of red hepatization and when dullness is well defined, the respiration is tubular. It is heard first with expiration (a point noted by James Jackson, Jr.), and is soft and of low pitch. Gradually it becomes more intense, and finally presents an intensity unknown in any other pulmonary affection—of high pitch, perfectly dry, and of equal length with inspiration and expiration. It is simply the propagation of the laryngeal and tracheal sounds through the bronchi and the consolidated lung tissue. The permeability of the bronchi is essential to its production. Tubular breathing is absent in the excessively rare cases of massive pneumonia in which the larger bronchi are completely filled with exudation. When resolution begins mucous râles of all sizes can be heard. At first they are small and have been called the *redux-crepitus*. The voice-sounds and the expiratory grunt are transmitted through the consolidated lung with great intensity and may have a curious nasal quality. There are cases in which the consolidation is deeply seated—so-called central pneumonia, in which the physical signs are slight or even absent, yet the cough, the rusty expectoration, and general features make the diagnosis certain.

CIRCULATORY SYMPTOMS.—During the chill the *pulse* is small, but in the

succeeding fever it becomes full and bounding. In cases of moderate severity it ranges from 100 to 120. It is not often dicrotic. In strong, healthy individuals and in children there may be no sign of failing pulse throughout the attack. With extensive consolidation the left ventricle may receive a diminished amount of blood and the pulse in consequence may be small. In the old and feeble it may be small and rapid from the outset. The pulse may be full, soft, very deceptive, and of no value whatever in prognosis.

Blood Pressure.—During the first few days there is usually no change. The extent of involvement seems to have no effect upon the blood pressure. In the toxic cases the pressure may begin to fall early; a drop of 15-20 mm. Hg is perfectly safe, but a progressive fall indicates the need of stimulation. A sudden drop is rarely seen except just before death. The crisis has no effect on the blood pressure. The opinion commonly held, that when the blood pressure as expressed in millimeters of Hg does not fall below the pulse rate expressed in beats per minute, the outlook is good, and *vice versa*, is by no means always correct. The heart sounds are usually loud and clear. During the intensity of the fever, particularly in children, murmurs are not uncommon both in the mitral and pulmonic areas. The second sound over the pulmonary artery is accentuated. Attention to this sign gives a valuable indication as to the condition of the lesser circulation. With distention of the right chambers and failure of the right ventricle to empty itself completely, the pulmonary second sound becomes much less distinct. When the right heart is engorged there may be an increase in the dullness to the right of the sternum. With circulatory failure the long pause is greatly shortened and the sounds approach each other in tone (embryocardia). There may be temporary auricular fibrillation, or extra-systoles may occur.

There may be a sudden early collapse of the heart with very feeble, rapid pulse and increasing cyanosis. This may happen on the third day. Even when these symptoms are very serious recovery may take place. In other instances without any special warning death may occur even in robust, previously healthy men. Some of these cases are due to heart block. The soft, easily compressed pulse, with the gray, ashy facies, cold hands and feet, the clammy perspiration, and the progressive prostration tell of a toxic action on the circulation.

Blood.—Pneumococci are present in the blood in about 30 per cent. of all cases. Anæmia is rare. A decrease in the red cells may occur at the time of the crisis. There is in most cases a leucocytosis, which appears early, persists, and disappears with the crisis. The leucocytes may number from 12,000 to 40,000 or even 100,000 per c. mm. The fall in the leucocytes is often slower than the drop in the fever, particularly when resolution is delayed or complications are present. The annexed chart gives a study by Chatard of the leucocytes in 582 cases at the Johns Hopkins Hospital. More than half of the patients, about 350, had a leucocytosis between 15,000 and 35,000, and one-third (198) between 20,000 and 30,000. The broken line represents the mortality which is high when the leucocytes are below 10,000, but steadily decreases and is lowest when they are between 20,000 and 30,000. With the leucocytes between 30,000 and 60,000 the mortality is again higher. The two patients with the highest leucocytosis of the series, 95,000 and 105,000 respectively, recovered. A striking feature in the blood-slide is the density

of the fibrin network. This corresponds to the great increase in the fibrin elements, the proportion rising from 4 to 10 parts per thousand. The blood-plates are greatly increased.

DIGESTIVE ORGANS.—The tongue is white and furred, and in severe toxic cases rapidly becomes dry. Vomiting is not uncommon at the onset in children. The appetite is lost. Constipation is more common than diarrhoea.

CHART IV.—BLOOD COUNT IN PNEUMONIA AND COMPARATIVE MORTALITY. CONTINUOUS LINE REPRESENTS NUMBER OF CASES OF PNEUMONIA. BROKEN LINE REPRESENTS MORTALITY PERCENTAGE OF SAME.

A distressing and sometimes dangerous symptom is meteorism. Fibrinous, pneumococcic exudates may occur in the conjunctivæ, nose, mouth, prepuce, and anus (Cary). The liver may be depressed by the large right lung, or enlarged from the engorged right heart or as a result of the infection. The spleen is usually enlarged.

SKIN.—Among cutaneous symptoms one of the most interesting is the association of herpes with pneumonia. Not excepting malaria, we see labial herpes more frequently in this than in any other disease, occurring in from

12 to 40 per cent. of the cases. It is supposed to be of favorable prognosis, and figures have been quoted in proof of this assertion. It may also occur on the nose, genitals, and anus. Its significance and relation to the disease are unknown. At the height of the disease sweats are not common, but at the crisis they may be profuse. Redness of one cheek is a phenomenon long recognized in pneumonia, and is usually on the same side as the disease. A diffuse erythema is occasionally seen, and in rare cases purpura. Jaundice is referred to among the complications.

URINE.—Early in the disease it presents the usual febrile characters of high color, high specific gravity, and increased acidity. A trace of albumin is very common. There may be casts, and in a few instances the presence of albumin, casts, and blood indicates an acute nephritis. The urea and uric acid are usually increased at first, but may be much diminished before the crisis, to increase greatly with its onset. Robert Hutchison's researches show that a true retention of chlorides within the body takes place, the average amount being about 2 grams daily. It is a more constant feature of pneumonia than of any other febrile disease, and a diminution of the chlorides in the urine may be of value in the diagnosis from pleurisy with effusion or empyema. It is to be remembered that in dilatation of the stomach chlorides may be absent. Hæmaturia is a rare complication.

CEREBRAL SYMPTOMS.—Headache is common. In children vomiting or convulsions may occur at the outset. Apart from meningitis, considered separately, one may group the cases with marked cerebral features into:

First, the so-called cerebral pneumonias of children, in which the disease sets in with a convulsion, and there are high fever, headache, delirium, great irritability, muscular tremor, and perhaps retraction of the head and neck with Kernig's sign and an extensor plantar reflex. The diagnosis of meningitis is usually made, and the local affection may be overlooked.

Secondly, the cases with maniacal symptoms. These may occur at the very outset, with no suspicion that the disease is other than acute mania.

Thirdly, alcoholic cases with the features of delirium tremens. It should be an invariable rule, even if fever be not present, to examine the lungs in a case of *mania à potu*.

Fourthly, cases with toxic features, rather resembling those of uræmia. Without a chill and without cough or pain in the side, a patient may have fever, a little shortness of breath, and then gradually grow dull mentally, and within three days be in profound toxæmia with low, muttering delirium.

It is stated that apex pneumonia is more often accompanied with severe delirium. Occasionally the cerebral symptoms occur after the crisis. Mental disturbance may persist during and after convalescence, and in a few instances delusional insanity follows, the outlook in which is favorable.

Hemiplegia may be due to thrombosis, embolism, abscess or œdema. Withington called attention to a form associated with encephalitis. It may be transient and recovery complete. Transient *aphasia*, with or without hemiplegia, may occur and there are cases in which no gross lesions have been found, so that it has been suggested that it is due to œdema or to a relative ischæmia. Inequality of the pupils is not uncommon but has no special significance.

The Crisis.—After the fever has persisted for from five to nine or ten

days there is an abrupt drop, known as the crisis, which is one of the most characteristic features of the disease. The day of the crisis is variable. It is very uncommon before the third day, and rare after the twelfth. We have seen it as early as the third day. From the time of Hippocrates it has been thought to be more frequent on the uneven days, particularly the fifth and seventh; the latter has the largest number of cases (Musser and Norris). A precritical rise of a degree or two may occur. In one case the temperature rose from 105° to nearly 107° , and then in a few hours fell to normal. The usual time is from five to twelve hours, but often in an hour there may occur a fall of six or eight degrees (S. West). The temperature may be sub-normal after the crisis, as low as 96° or 97° . Usually there is an abundant sweat, and the patient sinks into a comfortable sleep. The day after the crisis there may be a slight post-critical rise. A pseudo-crisis is not very uncommon, in which on the fifth or sixth day the temperature drops from 104° or 105° to 102° , and then rises again. When the fall takes place gradually within twenty-four hours it is called a protracted crisis. If the fever persists beyond the twelfth day, the fall is likely to be by lysis. In children this mode of termination is common, and occurred in one-third of a series of 183 cases reported by Morrill. Occasionally in debilitated individuals the temperature drops rapidly just before death; more frequently there is an ante-mortem elevation. In delayed resolution the fever may persist for six or eight weeks. The crisis, the most remarkable phenomenon of pneumonia, appears to represent the stage of active immunity to the toxin of the pneumococcus. The fever, dyspnoea and general symptoms disappear when the immunity reaches a certain stage. With the fall in the fever the respirations become reduced almost to normal, the pulse slows, and the patient passes from a state of hazard and distress to one of safety and comfort, and yet, so far as the physical examination indicates, there is with the crisis no special change in the condition in the lung. A termination by crisis occurs most often in Type I and least often in Type III infections.

Complications.—Compared with typhoid fever, pneumonia has but few complications and still fewer sequelæ. The most important are the following:

Pleurisy is an inevitable event when the inflammation reaches the surface of the lung, and thus can scarcely be termed a complication. But there are cases in which the pleuritic features take the first place. The exudation may be sero-fibrinous with copious effusion, differing from that of an ordinary acute pleurisy in the greater richness of the fibrin, which may form thick, tenacious, curdy layers. An extensive serous effusion may form very rapidly and cause extreme dyspnoea which may be regarded as due to the pneumonia. The error is serious as removal of the fluid may be necessary to save the patient's life. Pneumonia on one side with extensive pleurisy on the other is sometimes a puzzling complication to diagnose, and an aspirating needle may be required to settle the question. *Empyema* is a common complication occurring in 2.2 per cent. of clinical cases collected by Musser and Norris and in 3.6 per cent. of the Johns Hopkins Hospital series. The pneumococcus is usually present; in a few the streptococcus, in which case the prognosis is not so good. Some cases may be due to extension from or rupture of a small lung abscess. Recurrence of the fever after the crisis or persistence of it after

the tenth day, with sweats, leucocytosis, and an aggravation of the cough, are suspicious symptoms. The dulness persists at the base, or may extend. The breathing is feeble and there are no râles. The voice sounds may have a very nasal quality. Such a condition may be closely simulated by a layer of fibrinous exudate, or a thickened pleura. Exploratory aspiration may settle the question at once and should not be delayed. There are obscure cases in which the pus has been found only at operation, as the collection may be very small or interlobar. The X-rays often give aid. When empyema occurs it is nearly always present before the acute features of the pneumonia are over.

Abscess.—This occurred in 4 of the 100 autopsies. Usually the lung breaks down in limited areas and the abscesses are not large, but they may fuse and involve a considerable proportion of a lobe. The condition is recognized by the sputum, which is usually abundant and contains pus and elastic tissue, sometimes cholesterin crystals and hæmatoidin crystals. The cough is often paroxysmal and of great severity; usually the fever is remittent, or in protracted cases intermittent in character. When a case is seen for the first time it may be difficult to determine whether it is one of abscess of the lung or empyema which has perforated the lung. The X-ray examination is of aid in the diagnosis.

Gangrene.—This is most commonly seen in old debilitated persons. It was present in 3 of the 100 autopsies. It very often occurs with abscess. The gangrene is associated with the growth of the saprophytic bacteria on a soil made favorable by the presence of the pneumococcus or the streptococcus. Clinically, the gangrene is rendered very evident by the horribly fetid odor of the expectoration and its characteristic features. In some instances the gangrene may be found post mortem when clinically there has not been any evidence of its existence.

Pericarditis, one of the most serious of complications, was present in 35 of 658 patients in the Johns Hopkins Hospital (Chatard). It is often a terminal affair and overlooked. The mortality is very high; 31 of the 35 patients died. It was most frequently associated with pneumonia of the right lung. In only 3 cases was the amount of fluid above 500 c. c. Pleurisy is an almost constant accompaniment, not infrequently being purulent.

Endocarditis.—The valves on the left side are more commonly attacked, and particularly if the seat of arterio-sclerosis. It is especially liable to attack persons with old valvular disease. There may be no indicative symptoms even in very severe cases. It may, however, be suspected in cases (1) in which the fever is protracted and irregular; (2) when signs of septic mischief arise, such as chills and sweats; (3) when embolic phenomena appear. The frequent complication of meningitis with the endocarditis of pneumonia gives prominence to the cerebral symptoms in these cases. The physical signs may be deceptive. There are instances in which no cardiac murmurs have been heard. In others the occurrence under observation of a loud, rough murmur, particularly if diastolic, is extremely suggestive.

Ante-mortem clotting in the heart, upon which the old writers laid great stress, is very rare. *Thrombosis* in the peripheral veins is also uncommon. In 35 out of 44 cases which were fully reported, the thrombosis occurred during convalescence. It is almost always in the femoral veins. A rare complication is *embolism* of one of the larger arteries. In one instance

embolism of the femoral artery at the height of pneumonia necessitated amputation at the thigh. The patient recovered.

Meningitis, a most serious complication, varies at different times and in different regions. The Montreal series is rather exceptional, as 8 per cent. of the fatal cases had this complication. In twenty years at the Johns Hopkins Hospital there were 25 cases of pneumococcus meningitis, in 18 of which pneumonia was present. In 16 of the cases the organism was demonstrated in the cerebro-spinal fluid. Endocarditis was present in 7 of the 18 cases. The percentage of meningitis in the pneumonia cases was 2.4, which is lower than the figures of Musser and Norris of 3.5 per cent. in 4,883 autopsies. It usually comes on at the height of the fever, and in the majority of the cases is not recognized unless the base is involved, which is not common. Occurring later in the disease, it is more easily diagnosed. The prognosis is bad and few instances of recovery are on record. Peripheral neuritis is a rare complication.

Gastric complications are rare. Fussell drew attention to the occurrence of acute dilatation of the stomach. Persistent vomiting, sudden abdominal distention and collapse are the most common features. A croupous gastritis has been mentioned. The croupous colitis may induce severe diarrhoea. It is by no means uncommon to have early pain, either in the region of the umbilicus or in the right iliac fossa, and a suspicion of appendicitis is aroused; indeed, a catarrhal form of this disease may occur coincidently with the pneumonia. In other instances so localized may the pain be in the region of the pancreas, associated with meteorism and high fever, that the diagnosis of acute hæmorrhagic pancreatitis is made. Peritonitis is a rare complication, sometimes in the upper peritoneum, due to direct extension through the diaphragm. It is usually in the severer cases and not easy to recognize. In one case in which there was a friction along the costal border, which was thought to indicate a peritonitis, it was communicated from the diaphragmatic pleura. Meteorism is not infrequent, and is sometimes serious. In some cases it may be due to a defect in the action of the diaphragm, in others to an acute septic catarrh of the bowels, or to a toxic paresis of the walls, occasionally to peritonitis. Jaundice occurs with curious irregularity in different years. In Baltimore it was more common among the negro patients. It sets in early, is rarely very intense, and has not the characters of obstructive jaundice. There are cases in which it assumes a very serious form. The mode of production is not well ascertained. It does not appear to bear any definite relation to the degree of hepatic engorgement, and it is not always due to catarrh of the ducts. It does not appear to influence the prognosis unfavorably.

Parotitis occasionally occurs, commonly in association with endocarditis. In children, middle-ear disease is not an infrequent complication.

Nephritis does not often follow pneumonia.

Arthritis occurred in 5 of 658 cases at the Johns Hopkins Hospital (Howard). It may precede the onset, and the pneumonia, possibly with endocarditis and pleurisy, may occur as a complication. In other instances at the height of the pneumonia one or two joints may become red and sore or after the crisis has occurred pain and swelling may come on in the joints. It is a serious complication as recovery is often slow and a stiff joint may result.

Relapse.—There are cases in which from the ninth to the eleventh day the fever subsides, and after the temperature has been normal for a day or two a rise occurs and fever may persist for another ten days or even two weeks. Though this might be termed a relapse, it is more correct to regard it as an instance of an anomalous course or delayed resolution. When it does occur, the attack is usually abortive and mild. In one patient, with pneumonia of the right lower lobe, crisis occurred on the seventh day, and after a normal temperature for thirteen days he was discharged. That night he had a shaking chill, followed by fever and recurring chills with reappearance of the pneumonia. In a second case the crisis occurred on the third day, and there was recurrence of pneumonia on the thirteenth day.

Recurrence is more common in pneumonia than in any other acute disease. Rush gives an instance in which there were 28 attacks. Other authorities narrate cases of 8, 10, and even more attacks.

Convalescence is usually rapid, and sequelæ are rare. After the crisis, sudden death has occurred when the patient has got up too soon. With the persistence of fever and leucocytosis the affected side should be carefully examined for pleurisy. With a persistence of the dulness the physical signs may be obscure, but the use of an exploratory needle or the X-rays will help to clear the diagnosis. Empyema

Clinical Varieties.—Local variations are responsible for some of the most marked deviations from the usual type. *Apex pneumonia* is said to be more often associated with adynamic features and with marked cerebral symptoms. The expectoration and cough may be slight. *Migratory or creeping pneumonia* is a form which successively involves one lobe after the other. *Double pneumonia* has no peculiarities other than the greater danger connected with it. *Massive pneumonia* is a rare form, in which not alone the air-cells but the bronchi of an entire lobe or even of a lung are filled with the fibrinous exudate. The auscultatory signs are absent; there is neither fremitus nor tubular breathing, and on percussion the lung is absolutely flat. It closely resembles pleurisy with effusion. The moulds of the bronchi may be expectorated in violent fits of coughing.

CENTRAL PNEUMONIA.—The inflammation may be deep-seated at the root of the lung or centrally placed in a lobe, and for several days the diagnosis may be in doubt. It may not be until the third or fourth day that a pleural friction is detected, or that dulness or blowing breathing and râles are recognized. Sometimes the diagnosis has to be made from the general features.

PNEUMONIA IN INFANTS.—It is sometimes seen in the new-born. In infants it very often sets in with a convulsion. The apex of the lung seems more frequently involved than in adults, and the cerebral symptoms are more marked. The torpor and coma, particularly if they follow convulsions, and the preliminary stage of excitement, may lead to the diagnosis of meningitis. Pneumonic sputum is rarely seen in children.

PNEUMONIA IN THE AGED.—The disease may be latent and set in without a chill; the cough and expectoration are slight, the physical signs ill-defined and changeable, and the constitutional symptoms out of all proportion to the extent of the local lesion.

PNEUMONIA IN ALCOHOLIC SUBJECTS.—The onset is insidious, the symptoms masked, the fever slight, and the clinical picture usually that of delirium

tremens. The thermometer alone may indicate the presence of an acute disease. Often the local condition is overlooked, as the patient makes no complaint, and there may be very little dyspnoea, no cough, and no sputum.

TERMINAL PNEUMONIA.—The wards and the post-mortem room show a very striking contrast in their pneumonia statistics, owing to the occurrence of what may be called terminal pneumonia. During the winter months patients with arterio-sclerosis, heart disease, nephritis, etc., are not infrequently carried off by a pneumonia which may give few or no signs. In the Johns Hopkins Hospital series of 658 cases, there were 35 cases of this variety, 20 of which were associated with cardio-vascular and 14 with renal disease. There may be slight fever, with increase in the respirations, but the patient is near the end and perhaps not in a condition in which a thorough physical examination can be made. There is often no leucocytosis. In diabetic patients the disease often runs a rapid and severe course, and may end in abscess or gangrene.

SECONDARY PNEUMONIA.—This is met with chiefly in the specific fevers, particularly diphtheria, typhoid fever, typhus, influenza, and the plague. Anatomically, it rarely presents the typical form of red or gray hepatization. The surface is smoother, not so dry, and it is often a pseudo-lobar condition, a consolidation caused by closely set areas of lobular involvement. Histologically, it is characterized in many instances by a more cellular, less fibrinous exudate, which may also infiltrate the alveolar walls. Bacteriologically, the pneumococcus may be the dominant organism; but Friedländer's bacillus, streptococci, staphylococci, the influenza and colon bacillus have been found.

The symptoms of the secondary pneumonias often lack the striking definiteness of primary lobar pneumonia. The pulmonary features may be latent or masked altogether. There may be no cough and only a slight increase in the number of respirations. The lower lobe of one lung is most commonly involved, and the physical signs are obscure and rarely amount to more than impaired resonance, feeble breathing, and a few crackling râles.

EPIDEMIC PNEUMONIA is, as a rule, more fatal, and often displays minor complications which vary in different outbreaks. In some the cerebral manifestations are marked; in others, the cardiac; in others again, the gastrointestinal.

LARVAL PNEUMONIA.—Mild, abortive types are seen, particularly in institutions when pneumonia is prevailing extensively. A patient may have the initial symptoms of the disease, a slight chill, moderate fever, a few indefinite local signs, and herpes. The whole process may only last for two or three days, some authors recognize even a one-day pneumonia.

ASTHENIC, TOXIC, OR TYPHOID PNEUMONIA.—The toxic features dominate throughout; the local lesions may be slight and subjective phenomena absent. The nervous symptoms usually predominate. There are delirium, prostration, and early weakness. Very frequently there is jaundice. Gastro-intestinal symptoms may be present, particularly diarrhoea and meteorism. In such a case, seen about the end of the first week, it may be difficult to say whether the condition is one of asthenic pneumonia or one of typhoid fever with early localization in the lung. Here the Widal reaction and blood cultures are important aids. Possibly, too, there is a mixed infection, and the streptococcus pyogenes may be in large part responsible for the toxic features.

Association of Pneumonia with Other Diseases.—(a) *With Malaria.*

—A malarial pneumonia is described and thought to be prevalent in some parts of the United States. One hears of it, indeed, even where true malaria is rarely seen. Pneumonia is a common disease in the tropics and often attacks the subjects of malaria. The prognosis is bad in the æstivo-autumnal infections. A special form of pneumonia due to the malarial parasite is unknown. Yet there are cases reported by Craig and others in which in an acute malarial infection the features suggest pneumonia at the onset, but the parasites are found in the blood, and under the use of quinine the fever drops rapidly and the pneumonia symptoms clear. In some instances a chill in the course of an ordinary pneumonia is associated with a malarial infection.

(b) *Pneumonia and Tuberculosis.*—Subjects of chronic pulmonary tuberculosis may die of acute lobar pneumonia, but often it is surprising how well they do even with a severe attack. A point to be specially borne in mind is the fact that acute tuberculous pneumonia may set in with all the features and physical signs of lobar pneumonia.

For the consideration of the association of pneumonia with typhoid fever and influenza, the reader is referred to the sections on those diseases.

POST-OPERATION PNEUMONIA.—Before the days of anæsthesia, lobar pneumonia was a well-recognized cause of death after surgical injuries and operations. Norman Cheevers, in an early number of the Guy's Hospital Reports, called attention to it as one of the most frequent causes of death after surgical procedures, and Erichsen states that of 41 deaths after surgical injuries 23 cases showed signs of pneumonia. In the statistics collected by Homans the mortality due to lung complications after laparotomies ranged from 0.56 to 12.5. Operations on the stomach seem to be peculiarly liable to be followed by pneumonia. The cases may be divided into three groups: (1) Inhalation or anæsthesia pneumonia which may be lobar or broncho-pneumonia. (2) Hypostatic pneumonia due to enfeebled circulation. (3) Embolic cases with sudden onset which may simulate pneumonia very closely. It must be emphasized that some cases regarded as post-operative or post-traumatic pneumonia are really instances of collapse of the lung. Careful examination and an X-ray study should give the diagnosis.

ANÆSTHESIA PNEUMONIA.—The vapor of the anæsthetic may have a damaging influence on the bronchial and alveolar epithelium, but a more important influence is the aspiration of mucus and saliva into the air passages during the anæsthesia. Thorough disinfection of the mouth and throat before operation is a useful preventive measure. W. Pasteur called attention to a condition of massive collapse of the lungs. He published the statistics of lung complications at the Middlesex Hospital; following 3,559 abdominal operations there were 201 pulmonary complications, with 45 deaths. Among these pneumonia heads the list with 88 cases and 31 deaths. The complications are much more numerous in operations above the umbilicus. The pneumonia may be lobar or patchy and as a rule the signs are well marked within the first two days after operation. Collapse may involve both lower lobes or one lobe or one lung, and may simulate pneumonia very closely. When unilateral, the mediastinum and heart are drawn towards the affected side. It may come on with great suddenness and prove fatal. Pneumonia may follow collapse of the lung.

DELAYED RESOLUTION.—The lung is restored to its normal state by the liquefaction and absorption of the exudate. There are cases in which resolution takes place rapidly without any increase in (or, indeed, without any) expectoration; on the other hand, during resolution it is not uncommon to find in the sputum little plugs of fibrin and leucocytes which have been loosened from the air-cells and expelled by coughing. A variable time is taken in the restoration of the lung. Sometimes within a week or ten days the dulness is greatly diminished, the breath-sounds become clear, and, so far as physical signs are any guide, the lung seems perfectly restored. Delayed resolution occurs in from 3 to 4 per cent. of cases. Of 40 cases at the Johns Hopkins Hospital, 33 were males and 7 females; 23 of the patients were negroes, a very high incidence. The lower lobe is most frequently involved, 37 cases in this series, usually the right one and as a rule only one lobe. The duration was to the fourth week 5 cases, fifth week 10 cases, sixth week 4 cases, ninth week 3 cases, tenth, eleventh and twelfth weeks each one case. In one patient the left lung remained solid for eleven weeks and then cleared perfectly. Syphilis is apparently a contributing factor in some cases.

Clinically, there are several groups of cases: First, those in which the crisis occurs naturally, the temperature falls and remains normal; but the local features persist—well-marked flatness with tubular breathing and râles. Resolution may occur very slowly and gradually, taking from two to three weeks. In a second group the temperature falls by lysis, and with the persistence of the local signs there is slight fever, sometimes sweats and rapid pulse. The condition may persist for three or four weeks and during all this time there may be little or no sputum. The practitioner is naturally much exercised and dreads tuberculosis. In a third group the crisis occurs or the fever falls by lysis; but the consolidation persists, and there may be intense bronchial breathing, with few or no râles, or the fever may recur and the patient may die exhausted.

TERMINATION IN FIBROSIS.—The exudate may organize and the alveolar walls thicken with the gradual production of a chronic interstitial or fibroid pneumonia. In one pneumonia autopsy on a patient aged 58, dead on the thirty-second day from the initial chill, the right lung was solid and the cut surface grayish in color with a smooth, translucent appearance. This is most frequently seen as a sequence of delayed resolution in debilitated subjects. Milne found 10 instances of organization of the exudate among 150 fatal cases. The shortest duration in the series was twenty-three days.

Ordinary lobar pneumonia never terminates in tuberculosis. The instances of caseous pneumonia and softening which have followed an acute pneumonic process have been tuberculous from the outset.

Prognosis.—Pneumonia is one of the most fatal of all acute diseases, outranking even tuberculosis as a cause of death in some years. In America the mortality appears to be increasing. It varies greatly in different years.

The statistics of the clinic at the Johns Hopkins Hospital from 1889 to 1905 have been analyzed by Chatard. There were 658 cases with 200 deaths, a mortality of 30.4 per cent. Excluding 35 cases of terminal pneumonia, the percentage is 26.4. The death-rate among 245 negroes was very little above that of the whites. Greenwood and Candy in a study of the pneumonia statistics at the London Hospital from 1854-1903, a total of 5,097 cases, conclude

that the fatality of the disease has not appreciably changed in this period. In comparing the figures from various hospitals, there is an extraordinary uniformity in the mortality rate. Between the ages of 21-30 the mortality is about 20 per cent.; between the ages of 31-40, 30 per cent.; and then after each decade it rises, until above the age of 60 more than one-half die.

Age.—As Sturges remarks, the old are likely to die, the young to recover. Under one year it is more fatal than between two and five. Of 50 cases under 10 years of age, 4 died; of 119 cases under 20, 16 died (Chatard). Above sixty the death-rate is very high, amounting to 60 or 80 per cent.; 33 of 44 cases in our series. From the reports of its fatality in some places, one may say that to die of pneumonia is almost the natural end of old people.

Previous habits of life and the condition of bodily health at the time of the attack are most important factors. In analyzing a series of fatal cases one is very much impressed by the number of cases in which the organs show signs of degeneration. This applies particularly to the kidneys. In 25 of the 100 autopsies at the Montreal General Hospital the kidneys showed extensive interstitial changes. Individuals debilitated from sickness or poor food, hard drinkers, and that large class of hospital patients, composed of robust-looking laborers between the ages of forty-five and sixty, whose organs show signs of wear and tear, and who have by excesses in alcohol weakened the reserve power, fall an easy prey to the disease.

Bacteræmia.—The presence of pneumococci in the blood gives a grave prognosis. In the Bellevue Hospital series the mortality was almost seven times greater in the patients with bacteræmia than in those with negative blood cultures (Cecil).

Certain complications and terminations are particularly serious. The meningitis of pneumonia is almost always fatal. Endocarditis is extremely grave, more so than pericarditis. Much stress has been laid upon the factor of leucocytosis as an element in the prognosis. A very slight or complete absence of leucocytosis is rightly regarded as very unfavorable.

Toxæmia is an important prognostic feature, to which in a majority of the cases the degree of pyrexia and the extent of consolidation are entirely subsidiary. Marked nervous symptoms, dilatation of the heart, a pulse-rate persistently above 125, low blood pressure, marked cyanosis, œdema of the lungs, meteorism, scanty secretion of urine and severe exhaustion are unfavorable signs. With multilobar involvement the mortality is about double that when only one lobe is involved.

The determination of the type of organism is of assistance. The death-rate in Types I and II is from 25 to 30 per cent.; in Type III about 40 per cent., and in Type IV 15 per cent. These figures may show considerable variation in different years. A high degree of blood infection as shown by cultures is a bad omen.

Death is rarely due to direct interference with the function of respiration, even in double pneumonia. Sometimes it is caused by the extensive involvement with œdema of the other parts of the lung, usually with progressive weakness of the right heart. But death is most frequently due to the action of the toxin on the circulation, with circulatory failure.

Diagnosis.—No disease is more readily recognized in a large majority of the cases. The external characters, the sputum, and the physical signs

combine to make one of the clearest of clinical pictures. The ordinary lobar pneumonia of adults is rarely overlooked. Errors are particularly liable to occur in the intercurrent pneumonias, in those complicating chronic affections, and in the disease as met with in children, the aged, and drunkards. Acute pneumonic tuberculosis is frequently confounded with pneumonia. Pleurisy with effusion is not often mistaken except in children.

In nephritis, chronic heart-disease, cancer, etc., an acute pneumonia often ends the scene, and is frequently overlooked. In these cases the temperature is perhaps the best index, and should, more particularly if cough occurs, lead to a careful examination of the lungs. The absence of expectoration and of pulmonary symptoms may make the diagnosis very difficult.

In children there are two special sources of error: the disease may be entirely masked by the cerebral symptoms and the case mistaken for one of *meningitis*. It is remarkable in these cases how few indications there are of pulmonary trouble. Lumbar puncture is of great aid in such cases. The other condition is *pleurisy with effusion*, which in children often has deceptive physical signs. The breathing may be intensely tubular and tactile fremitus may be present. The exploratory needle is sometimes required to decide the question. In the old and debilitated a knowledge that the onset of pneumonia is insidious, and that the symptoms are ill-defined and latent, should put the practitioner on his guard and make him very careful in the examination of the lungs in doubtful cases. In chronic alcoholism the cerebral symptoms may completely mask the local process. The disease may assume the form of violent mania, but more commonly the symptoms are those of delirium *tremens*. In any case, rapid pulse, rapid respiration, and fever are symptoms which should invariably excite suspicion of pneumonia. The acute signs due to a *foreign body* in a bronchus are often mistaken for those of pneumonia.

Pneumonia is rarely confounded with pulmonary tuberculosis, but to differentiate *acute pneumonic tuberculosis* is often difficult. The attack may set in with a chill. It may be impossible to determine which condition is present until softening occurs and elastic tissue and tubercle bacilli appear in the sputum. A similar mistake is sometimes made in children. With *typhoid fever*, pneumonia is not infrequently confounded. There are instances of pneumonia with the local signs well marked in which the patient rapidly sinks into what is known as the typhoid state, with *dry tongue*, *rapid pulse*, and *diarrhoea*. The diagnosis from *broncho-pneumonia* is discussed under that disease. *Infarct of the lung* should be considered in patients with cardiac disease. The sputum is usually more bloody and the signs in the lung not as marked. *Collapse of the lung* may suggest pneumonia but the marked displacement of the heart to the affected side is important evidence. The X-ray study is decisive. The occurrence of *abdominal pain with involvement of a lower lobe* may lead to a diagnosis of *appendicitis*, especially in children. A proper examination should prevent this error.

In addition an exact etiological diagnosis should be made as rapidly as possible. If due to the pneumococcus the type should be determined from the sputum if obtainable, otherwise by puncture of the lung or blood culture.

Prophylaxis.—We do not know in how many cases pneumonia is an auto-infection, the lowered resistance due to exposure or to alcohol, or a trauma or anæsthetization, simply furnishing conditions which favor the spread and

growth of an organism already present. Individuals who have had pneumonia should be careful to keep the teeth in good condition, and the mouth and throat in as healthy a state as possible. Antiseptic mouth washes may be used.

The evidence suggests that there is value in vaccines as a preventive, but the immunity produced is of short duration. When done it should be regarded as an experiment and careful records kept.

We know practically nothing of the conditions under which the pneumococcus lives outside the body, or how it gains entrance in healthy individuals. Patients should be isolated more carefully than is the ordinary custom, especially in institutions. The sputum should be sterilized, and gauze or paper napkins used to receive it should be burned. Gauze should be held before the mouth of the patient during coughing.

Treatment.—Pneumonia is a self-limited disease and even under the most unfavorable circumstances it may terminate abruptly and naturally. So also, under the favoring circumstances of good nursing and care, the experience of many physicians in different lands has shown that pneumonia runs its course in a definite time, terminating sometimes spontaneously on the third or the fifth day, or continuing until the tenth or twelfth.

A specific action on the pneumococcus is claimed for optochin, a quinine derivative. It has a well-marked protective action against experimental infection in mice; encouraging, but scarcely good enough results to use the term specific have been reported clinically. It is given in amounts of 1.5 gm. per day in doses of 0.2 to 0.25 gm. Over-dosage is usually manifested by disturbances of vision.

Expt.*

(a) GENERAL MANAGEMENT.—The same careful hygiene of the bed and of the sick-room should be carried out as in typhoid fever. Everything should be done to make the patient comfortable, save him exertion and secure sufficient sleep. Whenever possible the patient should be in the open air if this adds to his comfort or improves his condition. It does both in the majority of cases. In cold weather he should have sufficient covering to keep him warm, but should not be overburdened by a heavy weight of clothes. A blanket and rubber sheet, under the mattress, which can be folded up over the bed prevent chilling from below. A hot-water bag should be kept at the feet. The patient is brought indoors when necessary for hydrotherapy. If the patient is indoors the room should be bright and thoroughly ventilated. Only one or two persons should be allowed in the room at a time. The clothing should be as light as possible; there is no advantage in a "pneumonia jacket." Even when not called for on account of high fever, the patient should be carefully sponged each day with tepid water. This should be done with as little disturbance as possible. Special care should be taken to keep the mouth and nose clean. The giving of an alkali, such as potassium citrate (gr. xv, 1 gm. four times a day) is advisable. Alcohol should be given to chronic alcoholics.

(b) DIET.—Plain water, a pleasant table water, or lemonade should be given freely. When the patient is delirious the water should be given at fixed intervals and by the bowel or subcutaneously if it is not taken by mouth. The food should be liquid and semi-solid consisting of milk and its modifications, ice cream, broths, custard, milk toast, cereals and eggs. Carbohydrate, as milk sugar or dextrose can be added to each feeding of milk, and as cane sugar to lemonade.

rel may be
and in
tension.

(c) BOWELS.—These can be kept open by simple laxatives, salines or enemata. Drastic purgation is not advisable. It is important to prevent meteorism, if possible, by care in the diet, giving water freely and preventing constipation. If present, measures for relief should be begun at once. Turpentine stupes, turpentine (3 ss, 15 c. c.) added to an enema, an asafetida enema and the use of the rectal tube, are helpful. Strychnine and pituitary extract hypodermically are also useful. If the stomach is distended a stomach tube should be passed.

(d) BLEEDING.—The reproach of Van Helmont, that "a bloody Moloch presides in the chairs of medicine," can not be brought against this generation of physicians. Before Louis' iconoclastic paper on bleeding in pneumonia it would have been regarded as almost criminal to treat a patient without venesection. We employ it much more than we did a few years ago, but more often late in the disease than early. To bleed at the very onset in robust, healthy individuals in whom the disease sets in with great intensity and high fever is good practice. Late in the course marked dilatation of the right heart is the common indication. The quantity of blood removed must be decided by the effect; small amounts are often sufficient.

(e) SPECIFIC TREATMENT.—The value of the antipneumococcic serum is established for Type I if begun in the first three days. The serum should be given intravenously as soon as possible in doses of 50-100 c. c. diluted one half with freshly prepared salt solution. This is repeated twice or thrice daily, four or five doses usually being necessary. A rise in temperature indicates further dosage. Immune bodies are found in the blood after the first injection and remain if the treatment is continued. It is well to give 0.5 c. c. of serum subcutaneously a few hours before the first intravenous injection to desensitize. The first injection should be given very slowly. Polyvalent serums should not be given and Type I serum given only to proved Type I infections. The results from the use of antibody solutions (Huntoon, Felton) are encouraging. They are most useful in the early stages of the attack. The concentrated serum of Felton contains antibodies for the three fixed types. There is no proof that the use of vaccines is of value in treatment.

(f) HYDROTHERAPY.—This—internal and external—is our principal means of combating toxæmia and circulatory failure. Cold sponging is usually the best measure, done every three hours and with the least possible disturbance of the patient. A large flat ice bag may be kept to the side or back constantly, unless it causes distress. Probably the best effect of hydrotherapy is on the vasomotor system.

(g) SYMPTOMATIC TREATMENT.—(1) *To Relieve Pain.*—The stitch in the side at onset, which is sometimes so agonizing, is best relieved by a hypodermic injection of morphia (gr. $\frac{1}{4}$, 0.016 gm.). When the pain is less intense and diffuse a hot water bag or mustard poultice may be applied but the ice bag is usually more efficacious. When the disease is fairly established the pain is not, as a rule, distressing, except when the patient coughs, and for this codein (gr. $\frac{1}{2}$, 0.03 gm.), heroin (gr. $\frac{1}{12}$, 0.005 gm.), may be used or morphia hypodermically (gr. $\frac{1}{6}$, 0.01 gm.), according to the patient's needs.

(2) *To Combat Toxæmia.*—Abundance of water should be given to promote the flow of urine, and fluid given by bowel or subcutaneously if necessary but care must be taken not to give too large an amount subcutaneously if the

Morphine is of use in cases where pain is so great as to restrict expansion. Then, care may be seen with morphine but acet. more effective in other cases, where

circulation is failing; 500 c. c. is usually sufficient. In toxic patients the administration of glucose solution intravenously (250-300 c. c. of a 10 per cent. solution) two or three times a day may be helpful. External hydrotherapy should be kept up actively. The bowels should be kept open by laxatives or enemas.

(3) An all-important indication is to support the circulation. Hydrotherapy and keeping the patient out of doors are of great value for this. Mechanical disturbance, as from meteorism, should be prevented if possible. Drugs should not be given in any routine way and not until they are required. Strychnine is useful (also for its effects on the respiratory centre). It should be given hypodermically and in full doses (gr. $\frac{1}{20}$, 0.003 gm., and even gr. $\frac{1}{10}$, 0.006 gm., for short periods) every two or three hours. Atropine is useful, especially when there is excessive secretion or pulmonary œdema, and should be given in full doses hypodermically. In severe cases it is well to begin the use of digitalis early in the form of the tincture (℥ xv, 1 c. c.) three or four times a day. With signs of weakness of the circulation, intramuscular injections of one of the digitalis preparations are advisable. In severe conditions the use of strophanthin is often more efficient (gr. $\frac{1}{100}$, 0.0006 gm.) intramuscularly or intravenously. This may be repeated once in twelve or twenty-four hours. For severe circulatory failure caffeine (sodio-benzoate) gr. v. (0.3 gm.), or epinephrine solution (℥ xv, 1 c. c.) may be given hypodermically. Pituitary extract (posterior lobe) has been warmly recommended. An injection of hot saline solution given in the bowel or saline subcutaneously is helpful.

(4) Respiratory Tract.—The most comfortable position, avoidance of exertion, and abundance of fresh air are important aids in preventing dyspnoea. Pain should be relieved as much as possible. Expectorant drugs are not indicated and often upset the stomach. When the cough is severe it is well to give sedatives, of which codein and heroin are the best. Morphia in small doses may be required, but these drugs should be given only when necessary. For œdema of the lungs digitalis or strophanthin should be given intramuscularly and atropine (gr. $\frac{1}{100}$, 0.0006 gm.) and caffeine hypodermically. Venesection is advisable if the right heart be dilated. The dosage of atropine should be governed by the degree of œdema and the results. There should be no hesitation in giving large doses when required.

(5) Oxygen.—The occurrence of cyanosis is an indication for its use. The oxygen chamber is rarely available. Tents and masks are useful if the patient is not disturbed by them. A nasal tube may be the only method possible; about 2 litres of oxygen per minute should be given.

(6) Nervous System.—The patient with delirium should be constantly watched. An ice bag to the head and frequent sponges are useful. Sleep is important for every patient and the need for this is often forgotten. While such drugs as the bromides, chloral hydrate and barbital may be effectual, it is wiser, as a rule, to give morphia hypodermically in a sufficient dose (gr. $\frac{1}{4}$, 0.016 gm.) to secure rest and sleep.

(7) Crisis.—As this approaches constant watch should be kept for signs of collapse. If sweating is profuse and the patient feeble, atropine (gr. $\frac{1}{50}$, 0.0013 gm.) should be given hypodermically with epinephrine and repeated as necessary.

(h) TREATMENT OF COMPLICATIONS.—As empyema usually is a complication care should be taken to recognize it early. If present aspiration should be done at once as by this some cases clear promptly. If aspiration is not effectual drainage is necessary and should be done early. The occasional serous effusion should be aspirated promptly. In a complicating pericarditis with a large effusion aspiration may be necessary. Delayed resolution is a difficult condition to treat. The use of the X-rays is perhaps the most effective treatment, but tuberculosis should be excluded. Vaccine treatment has been useful in some cases.

(i) CONVALESCENCE.—The diet should be increased as rapidly as possible, the patient kept out of doors and after an ordinary attack allowed up in about a week. If the heart has suffered rest should be more prolonged.

B. BRONCHO-PNEUMONIA

(*Lobular Pneumonia, Capillary Bronchitis*)

Definition.—A bacterial infection of the finer bronchi and their related lobules. The process begins with inflammation of the bronchioles and smaller bronchi, a capillary bronchitis, which extends to the alveoli and the whole lobule or a group of lobules becomes filled with exudate, cellular and hæmorrhagic but distinctly less fibrinous than in lobar pneumonia.

Etiology.—Broncho-pneumonia occurs either as a primary or as a secondary affection. The relative frequency in 443 cases is thus given by Holt: Primary, without previous bronchitis, 154; secondary to bronchitis of the larger tubes, 41; to measles, 89; to whooping-cough, 66; to diphtheria, 47; to scarlet fever, 7; to influenza, 6; to varicella, 2; to erysipelas, 2; and to acute ileo-colitis, 19. The proportion of primary to secondary forms as shown in this list is probably too low.

PRIMARY ACUTE BRONCHO-PNEUMONIA attacks those of any age and is not uncommon in adults. The etiological factors are very much those of lobar pneumonia, and probably the pneumococcus is often associated with it.

SECONDARY BRONCHO-PNEUMONIA occurs in two great groups: (a) As a sequence of the infectious fevers—measles, diphtheria, whooping-cough, scarlet fever, etc. In children it forms the most serious complication of these diseases, and in reality causes more deaths than are due directly to the fevers. Following, as it does, the contagious diseases which principally affect children, we find that a large majority of cases occur during early life. According to Morrill's Boston statistics, it is most fatal during the first two years of life. The number of cases increases or decreases with the prevalence of measles, scarlet fever, and diphtheria. It is most prevalent in the winter and spring months. In the febrile affections of adults broncho-pneumonia is not very common. Thus in typhoid fever it is not so frequent as lobar pneumonia, though isolated areas of consolidation at the bases are by no means rare in protracted cases. In old people it may follow debilitating causes of any sort, and is met with in chronic nephritis and various acute and chronic maladies.

(b) In the second division are embraced the cases of so-called aspiration or deglutition pneumonia. Whenever the sensitiveness of the larynx is be-

numbered, as in the coma of apoplexy or uræmia, minute particles of food or drink may enter the trachea, and, reaching the smaller tubes, excite an intense inflammation similar to the vagus pneumonia which follows the section of the pneumogastrics in the dog. Cases are common after operations about the mouth and nose, after tracheotomy, and in cancer of the larynx and œsophagus. The aspirated particles in some instances induce such an intense broncho-pneumonia that suppuration or gangrene supervenes. The ether pneumonia may be lobular in type.

An aspiration broncho-pneumonia may follow hæmoptysis, the aspiration of material from a bronchiectatic cavity, and occasionally the material from an empyema which has ruptured into the lung. A common and fatal form of broncho-pneumonia is that excited by the tubercle bacillus.

Among general predisposing causes may be mentioned age. It is prone to attack infants, and a majority of cases of pneumonia in children under five years of age are of this form. Of 370 cases in children under five years of age, 75 per cent. were broncho-pneumonia (Holt). At the opposite extreme of life it is also common, in association with influenza and with various debilitating circumstances and chronic diseases. In children, rickets and diarrhoea are marked predisposing causes, and broncho-pneumonia is one of the most frequent post mortem lesions in infants' homes and foundling asylums. The disease prevails most extensively among the poorer classes.

Morbid Anatomy.—On the pleural surfaces, particularly toward the base, are seen depressed bluish or blue-brown areas of collapse, between which the lung tissue is of a lighter color. Here and there are projecting portions over which the pleura may be slightly turbid or granular. The lung is fuller and firmer than normal, and, though in great part crepitant, solid, nodular bodies can be felt in places throughout the substance. The dark depressed areas may be isolated or a large section of one lobe may be in the condition of collapse. Inflation by a blow-pipe in the bronchus will distend a great majority of these collapsed areas. On section, the general surface has a dark reddish color and usually drips blood. Projecting above the level of the section are lighter red or reddish-gray areas representing the patches of broncho-pneumonia. These may be isolated and separated from each other by tracts of uninfamed tissue or they may be in groups; or the greater part of a lobe may be involved. Study of a favorable section of an isolated patch shows: (a) A dilated central bronchiole full of tenacious purulent mucus. A fortunate section parallel to the long axis may show a racemose arrangement—the alveolar passages full of muco-pus. (b) Surrounding the bronchus for from 3 to 5 mm. or even more, an area of grayish-red consolidation, usually elevated above the surface and firm to the touch. It may present a perfectly smooth surface, though in some instances it is distinctly granular. In a late stage small grayish-white points may be seen, which on pressure may be squeezed out as purulent droplets. A section in the axis of the lobule may present a somewhat grape-like arrangement, the stalks and stems representing the bronchioles and alveolar passages filled with a yellowish or grayish-white pus, while surrounding them is a reddish-brown hepatized tissue. (c) In the immediate neighborhood of this peribronchial inflammation the tissue is dark in color, smooth, airless, at a somewhat lower level than the hepatized portion, and differs distinctly in color and appearance from the other portions of the

lung. This is the condition to which the term *splenization* has been given. It really represents a tissue in the early stage of inflammation, and it would be well to give up the use of this term and also that of *carnification*, which is only a more advanced stage.

There are three groups of cases: (1) Those in which the bronchitis and bronchiolitis are most-marked, and in which there may be no definite consolidation, and yet on microscopic examination many of the alveolar passages and adjacent air-cells appear filled with inflammatory products. (2) The disseminated broncho-pneumonia, in which there are scattered areas of peribronchial hepatization with patches of collapse, while a considerable proportion of the lobe is still crepitant. This is by far the most common condition. (3) The pseudo-lobar form, in which the greater portion of the lobe is consolidated, but not uniformly, for intervening strands of dark congested lung tissue separate the groups of hepatized lobules.

Microscopically, the centre of the bronchus is seen filled with a plug of exudation, consisting of leucocytes and swollen epithelium. Section in the long axis may show irregular dilatations of the tube. The bronchial wall is swollen and infiltrated with cells. The air-cells next the bronchus are mostly densely filled, while toward the periphery the alveolar exudation becomes less. The contents of the air-cells are made up of leucocytes and swollen epithelial cells in varying proportions. Red corpuscles are not often present and a fibrin network is rarely seen, though it may be present in some alveoli. In the swollen walls are seen distended capillaries and numerous leucocytes. As Delafield pointed out, the *interstitial inflammation of the bronchi and alveolar walls* is the special feature of broncho-pneumonia.

The histological changes in the aspiration or deglutition broncho-pneumonia differ from the ordinary post-febrile form in a more intense infiltration of the air-cells with leucocytes, producing suppuration and foci of softening; even gangrene may be present.

Bacteriology.—The organisms most commonly found are the pneumococcus, *Streptococcus pyogenes* (either alone or with the pneumococcus), *Staphylococcus aureus et albus*, Friedländer's *Bacillus pneumoniae*, and the influenza bacillus. The Klebs-Loeffler bacillus is not infrequently found in the secondary lesions of diphtheria. Except the pneumococcus these microbes are rarely found in pure cultures. In the lobular type the streptococcus is the most constant organism, in the pseudo-lobar the pneumococcus. Mixed infections are almost the rule in broncho-pneumonia.

Terminations of Broncho-pneumonia.—(a) In *resolution*, which when it once begins goes on more rapidly than in fibrinous pneumonia. Broncho-pneumonia of the apices, in a child, persisting for three or more weeks, particularly if it follow measles or diphtheria, is often tuberculous. In these instances, when resolution is supposed to be delayed, caseation has in reality taken place. (b) In *suppuration*, which is rarely seen apart from the aspiration and deglutition forms, in which it is extremely common. (c) In *gangrene*, which occurs under the same conditions. (d) In *fibroid changes—chronic broncho-pneumonia*—a rare termination in the simple, a common sequence of the tuberculous, disease. When due to Friedländer's bacillus the consolidation may resolve very slowly, almost be chronic, and simulate pulmonary tuberculosis.

Symptoms.—The primary form sets in abruptly with a chill or a convulsion. The patient has not had a previous illness, but there may have been slight exposure. The temperature rises rapidly and is more constant; the physical signs are more local and there is not the widespread diffuse catarrh of the smaller tubes. Many cases are mistaken for lobar pneumonia. In others the pulmonary features are in the background or are overlooked in the intensity of the general or cerebral symptoms. The termination is often by crisis, and the recovery is prompt. The mortality of this form is slight. It is important to recognize the frequency of these primary cases and their resemblance to lobar pneumonia. The primary form is not uncommon in adults and as a rule the attack is not severe.

The secondary form begins usually as a bronchitis of the smaller tubes. Much confusion has arisen from the description of capillary bronchitis as a separate affection, whereas it is only a part, though a primary and important one, of broncho-pneumonia. It may be said that if in convalescence from measles or whooping-cough a child has an accession of fever with cough, rapid pulse, and rapid breathing, and if, on auscultation, fine râles are heard at the bases, or widely spread throughout the lungs, even though neither consolidation nor blowing breathing can be detected, the diagnosis of broncho-pneumonia may safely be made. The onset is rarely sudden, or with a distinct chill; but after a day or so of indisposition the child becomes feverish and begins to cough and be short of breath. The fever is extremely variable; a range of from 102° to 104° is common. The skin is very dry and hot. The cough is hard, distressing, and may be painful. Dyspnoea gradually becomes a prominent feature. Expiration may be jerky and grunting. The respirations may rise as high as 60 or even 80 per minute. Within the first forty-eight hours the percussion resonance is not impaired; the note, indeed, may be very full at the anterior borders of the lungs. Percussion yields varying notes; tympany may be adjacent to dulness which depends on areas of consolidation or collapse near the surface. On auscultation, many râles are heard, chiefly the fine subcrepitant variety, with sibilant rhonchi. There may really be no signs indicating that the parenchyma of the lung is involved, and yet even at this early stage, within forty-eight hours of the onset of pulmonary symptoms, scattered nodules of lobular hepatization may be found. Collapse of small areas of lung tissue is probably common and explains some of the sudden changes in signs over a given area. The dyspnoea is constant and progressive and cyanosis is marked in severe cases. The face becomes a little suffused and the finger-tips bluish. The patient has an anxious expression and gradually enters upon the most distressing stage of asphyxia. At first the urgency of the symptoms is marked, but soon the influence of the toxins is seen and there are no longer strenuous efforts to breathe. The cough subsides, and, with a gradual increase in lividity and a drowsy restlessness, the right ventricle becomes more and more distended, the bronchial râles become more liquid as the tubes fill with mucus, and death follows. These are symptoms of a severe case of broncho-pneumonia, or what the older writers called suffocative catarrh.

The PHYSICAL SIGNS may at first be those of capillary bronchitis, as indicated by the absence of dulness and the presence of fine subcrepitant and whistling râles. In many cases death takes place before any definite pneumonic signs are detected. When these exist they are much more frequent at

the bases, where there may be areas of impaired resonance or even of positive dullness. When numerous foci involve the greater part of a lobe the breathing may become tubular, but in the scattered patches of ordinary broncho-pneumonia, following the fevers, the breathing is more commonly harsh than blowing. In grave cases there is retraction of the base of the sternum and of the lower costal cartilages during inspiration, pointing to deficient lung expansion. The duration is usually longer than in lobar pneumonia or in the primary form. The termination is by lysis and convalescence is prolonged. There is a group in which an area of consolidation at the base may persist for some time, weeks or months.

Complications are not common. Empyema may occur, sometimes of small extent and the area may be walled off, making diagnosis difficult. Abscess and gangrene occur most often in the aspiration cases and in debilitated persons. Endocarditis, pericarditis, meningitis, otitis media, etc., are occasional complications. Of sequels the most important is fibrosis which may be local. Associated with or due to it are some cases of bronchiectasis.

Diagnosis.—The clinical picture is so variable that no exact rules can be given. In some cases the diagnosis is made from the symptoms and general condition rather than from the physical signs. The most frequent error is to miss a broncho-pneumonia rather than to confuse it with some other disease. A suspicion of broncho-pneumonia is usually justified. In the primary form there is rarely much difficulty in recognizing pneumonia but the distinction from the lobar form may not be easy. Broncho-pneumonia is bilateral; even with large areas of consolidation this rarely involves the whole of a lobe; it tends to involve the lower lobes, and its physical signs are rarely so definite. The consolidation of broncho-pneumonia may be variable from day to day (probably due to varying grades of collapse) and is usually patchy. The breath-sounds show change if small areas are carefully observed with comparison of the adjacent lung, and the whispered voice may be unusually clear and nasal in quality. In the secondary form, the increase in fever with cough, the rise in the respiration rate, cyanosis, toxæmia and signs usually most marked in the lower lobes, suggest the diagnosis.

For the student the distinction from acute bronchitis perhaps gives the greatest difficulty. Bronchitis alone is not a serious disease, the temperature is not high, dyspnoea is slight or absent, there is rarely cyanosis, and the only physical sign is the occurrence of medium or coarse râles. The presence of fine crackling râles, especially in the lower lobes, should always suggest pneumonia. A severe "bronchitis" with marked general features is usually broncho-pneumonia. If the student remembers that the areas involved vary from multiple minute "dots" to consolidation of a lobe, with every gradation between, the variation in the physical signs will cause less difficulty. In children the signs caused by a foreign body in a bronchus may be mistaken for those of broncho-pneumonia.

In many instances the decision whether a broncho-pneumonia is simple or tuberculous cannot be made, as the mode of onset and the physical signs may be identical. There are many cases of broncho-pneumonia which time alone enables us to distinguish from tuberculosis. The existence of extensive disease at the apices or central regions is a suggestive indication, and signs of softening may be detected.

Some forms show special features, as, for example, the broncho-pneumonia of *influenza*. In that due to the *hæmolytic streptococcus* the features are severe with marked toxæmia, dyspnoea and cyanosis, bloody sputum and a remarkable frequency of empyema which may come on very rapidly. The picture is that of a severe septic infection.

Cerebral symptoms may mask the true nature of the disease, as in lobar pneumonia, and lead to the diagnosis of meningitis. Lumbar puncture or autopsy may be necessary to determine whether the child had tuberculous meningitis or a cerebral complication of an acute pulmonary affection.

Prognosis.—In the primary form the outlook is good. In children enfeebled by constitutional disease and prolonged fevers broncho-pneumonia is terribly fatal, but in cases coming on in connection with whooping-cough or after measles recovery may take place in the most desperate cases. It is in this disease that the truth of the old maxim is shown—"Never despair of a sick child." The death-rate in children under five has been variously estimated at from 30 to 50 per cent. After diphtheria and measles thin, wiry children seem to stand broncho-pneumonia much better than fat, flabby ones. In adults the aspiration or deglutition pneumonia is very fatal.

Prophylaxis.—Much can be done to reduce the probability of attack after febrile affections. Thus, in the convalescence from measles and whooping-cough, it is very important that the child should not be exposed to cold, particularly at night, when the temperature of the room naturally falls. The use of light flannel "combinations" obviates this nocturnal chill, which is an important factor in the colds and pulmonary affections of young children. Catarrhal troubles of the nose and throat should be carefully attended to, and during fevers the mouth should be washed two or three times a day with an antiseptic solution.

Treatment.—The frequency and the seriousness of broncho-pneumonia render it a disease which taxes to the utmost the resources of the practitioner. There is no acute pulmonary affection over which he at times so greatly despairs. On the other hand, there is not one in which he will be more gratified in saving patients who have seemed past all succor. The general measures are much as in lobar pneumonia. The patient should be in the open air if a trial shows that he is more comfortable than inside; if indoors, the windows should be wide open with the patient protected from drafts.

(a) **DIET.**—As much food as possible should be given. Milk and its modifications, ice cream, eggs, broths, cocoa, and gruels are suitable. Water should be given freely by mouth and if this is not possible by the bowel or subcutaneously. The bowels should be opened by castor oil or calomel and care taken to secure a daily movement by simple laxatives or enema. Severe purgation should be avoided.

(b) **HYDROTHERAPY.**—This may be given by various methods to be chosen for each patient, depending on the condition and results. Sponges may be given to any patient. Packs are useful, hot if there is much restlessness or cold if the temperature is high, or baths may be given to children for short periods, using water at 95° F. and gradually reducing to 75° or 80° F. Compresses, made out of linen covered by flannel or of flannel alone, wrung out of water 60° to 70°, are often useful. They should not be covered by oiled silk. A mustard bath is of value for children, especially early in the attack.

Hydrotherapy is especially indicated for patients with high fever, delirium or stupor, severe toxæmia, or circulatory failure.

(c) **LOCAL APPLICATIONS.**—Poultices have gone out of fashion but are sometimes of value. They should be light and are best kept in place by being slipped in pockets in a flannel jacket which is constantly worn so that the poultice can be replaced without disturbing the patient. The use of dry cups is often advised; they should be applied frequently. The ice bag should be used if it gives comfort.

(d) **MEDICINAL.**—The indications must be carefully studied and drugs which may disturb the stomach given with care. If cough is distressing the use of the compound tincture of benzoin in an inhalation should be tried. The expectorant drugs may aid and of these ammonium chloride (gr. ii to v, 0.13 to 0.3 gm.) and the wine of ipecacuanha (℥ x to xx, 0.6 to 1.3 c. c.) are the most useful. To these a sedative, such as paregoric (℥ i, 4 c. c.), codein (gr. ¼, 0.016 gm.) or heroin (gr. 1-20, 0.0032 gm.) should be added if the cough is very distressing. Strychnine hypodermically (gr. 1-40 to 1-20, 0.0016 to 0.0032 gm.) is an aid to the respiratory centre and to the circulation. For circulatory failure the treatment is the same as described under lobar pneumonia. With increasing difficulty in getting up the secretions an emetic may be given, but only to robust patients. Ipecacuanha or apomorphine hypodermically should be employed. Inhalations of oxygen are advisable if they give relief to the dyspnœa and lessen cyanosis.

In old persons early stimulation is usually advisable and every effort should be made to persuade them to take nourishment. Cold applications must be used with caution and the use of heat is generally better. At all ages frequent change in position is advisable and in young children this may be done by taking them out of bed and holding them in the arms.

C. OTHER PNEUMOCOCCIC INFECTIONS

The organism is widely distributed and causes a number of affections other than pulmonary, of which the following are the most important:

(1) **Acute Septicæmia.**—Without any recognized local lesion there may be a general infection with the pneumococcus. The features are those of an acute general infection and death may result in a short time. The diagnosis can only be made by blood culture.

(2) **Local Affections.**—The local affections caused by the pneumococcus are numerous and are described under their appropriate sections. In the mouth, erosions, gingivitis and glossitis; in the pharynx, inflammation and tonsillitis; in the ear, acute and chronic suppuration; in the accessory sinuses, of which it is a common habitant, inflammation and suppuration; it is a common cause of primary and secondary meningitis; in the bronchi it has been found associated with acute and chronic bronchitis, and bronchiectasis; in the lungs, in addition to the two important diseases already considered, it may cause acute œdema and is associated with tuberculosis and many chronic affections. It has been found in acute pleurisy and it is one of the common causes of empyema; acute arthritis, primary and secondary forms; acute peritonitis, particularly in children; appendicitis; endocarditis; pyelitis and local abscesses in various parts may be caused by it.

IX. CEREBRO-SPINAL FEVER

Definition.—An infectious disease, occurring sporadically and in epidemics, caused by the *meningococcus*, characterized by inflammation of the cerebro-spinal meninges and a clinical course of great irregularity.

The affection is also designated *meningococcus meningitis*, *spotted fever* and *epidemic cerebro-spinal meningitis*.

History.—Viesseux first described a small outbreak in Geneva in 1805. In 1806 L. Danielson and E. Mann (Medical and Agricultural Register, Boston) gave an account of "a singular and very mortal disease which lately made its appearance in Medfield, Mass." The Massachusetts Medical Society, in 1809, appointed James Jackson, Thomas Welch, and J. C. Warren to investigate it. Elisha North's little book (1811) gives a full account of the early epidemics. Stillé's monograph (1867) and the elaborate section in vol. i of Joseph Jones' works contain details of the later American outbreaks. In his Geographical Pathology, Hirsch divides the outbreaks into four periods: From 1805 to 1830, in which the disease was most prevalent throughout the United States; a second period, from 1837 to 1850, when the disease prevailed extensively in France, and there were a few outbreaks in the United States; a third period, from 1854 to 1874, when there were outbreaks in Europe and several extensive epidemics in America. During the Civil War there were comparatively few cases. It prevailed extensively in the Ottawa Valley early in the seventies. In the fourth period, from 1875 to the present time, the disease has broken out in a great many regions. In the United States, during 1898-1899, it prevailed in mild form in 27 states and since 1899 there have been extensive outbreaks on the Atlantic coast. In New York in 1904-'05 there were 6,755 cases and 3,455 deaths. In Glasgow in 1907 there were nearly 1,000 cases with 595 deaths (Chalmers). In Belfast in the eighteen months ending June, 1908, there were 725 cases with 548 deaths (Robb). There were 1,974 deaths in England and Wales in 1915, the average for the five years before being 153, and 438 deaths in 1928. In the winter of 1914-'15 the disease was carried by Canadian troops to England. It broke out in many home camps and, spreading to the civil population, for the first time the disease prevailed widely in England.

Etiology.—Cerebro-spinal fever occurs in epidemic and in sporadic forms. The *epidemics* are *localized* and are rarely very widespread. Only in the tropics have there been extensive killing pandemics. As a *rule*, *country districts* have been *more afflicted than cities*. *Mining districts and seaports* have suffered most severely. The outbreaks have occurred most frequently in the *winter and spring*. The *concentration of individuals, as of troops in barracks*, is a special factor; recruits and young soldiers are specially liable. In civil life children and young adults are most susceptible. *Over-exertion, depressing mental and bodily surroundings, and the misery and crowding of the tenement houses in cities* are *predisposing causes*. The disease is not highly infectious. It is very rare to have more than one or two cases in a house, and in a city epidemic the distribution of the cases is very irregular. The organism enters and leaves the body by the naso-pharyngeal mucous membrane, and hence infection may be by contact or by coughing and sneezing. *Meningitis carriers*

play an important rôle in transmitting the disease. They are found also when the disease is not epidemic.

Sporadic Cerebro-spinal Fever.—The disease lingers indefinitely after an outbreak, and in all large cities cases occur. The posterior basic meningitis of Gee and Barlow has been shown to be due to the meningococcus.

Bacteriology.—In 1877 Weichselbaum described the *meningococcus* or *Micrococcus (intracellularis) meningitidis*. In the tissues the organism is almost constantly within the polynuclear leucocytes. Investigations have shown that there are four fixed types, and perhaps others, distinguishable from one another by immune reactions. Types I and II are said to be more likely to involve the meninges and III and IV to cause septicæmia and metastases. The type of organism in the cerebro-spinal fluid is the same as in the naso-pharynx and apparently if one variety infects the mucous membrane it is not likely that another will be superimposed on it. The use of agglutination tests has been of great value in identifying the organism. The presence of the organism in the naso-pharynx both in patients and in healthy contacts (carriers) is an important point. The meningococcus may be in the blood without meningitis resulting. There is “up and down” fever and possibly arthritis and skin lesions. Occasionally the blood infection is present before meningitis occurs.

Morbid Anatomy.—In malignant cases there may be no characteristic changes, the brain and spinal cord showing only extreme congestion, which was the lesion described by Vieusseux. In a majority of the acutely fatal cases death occurs within the first week. There is intense injection of the pia-arachnoid. The exudate is usually fibrino-purulent, most marked at the base of the brain, where the meninges may be greatly thickened and plastered over with it. On the cortex there may be much lymph along the larger fissures and in the sulci; sometimes the entire cortex is covered with a thick, purulent exudate. It deserves to be recorded that Danielson and Mann made five autopsies and were the first to describe “a fluid resembling pus between the dura and pia mater.” The cord is always involved with the brain. The exudate is more abundant on the posterior surface, and involves, as a rule, the dorsal and lumbar regions more than the cervical portion.

In the more chronic cases there is general thickening of the meninges and scattered yellow patches mark where the exudate has been. The ventricles in the acute cases are dilated and contain a turbid fluid, or in the posterior cornua pure pus. In the chronic cases the dilatation may be very great. The brain substance is usually a little softer than normal and has a pinkish tinge; foci of hæmorrhage and of encephalitis may be found. The cranial nerves are usually involved, particularly the second, fifth, seventh, and eighth. The spinal nerve roots are also found imbedded in the exudate.

Microscopically, the exudate consists largely of polynuclear leucocytes closely packed in a fibrinous material. In some instances there are foci of purulent infiltration and hæmorrhage. The neuroglia cells are swollen, with large, clear, and vesicular nuclei. The ganglion cells show less marked changes. Meningococci are found in variable numbers in the exudate, being more numerous in the brain than in the cord.

The sphenoidal sinuses may be full of pus and the surrounding bone inflamed. The frequency of catarrhal and other changes in the naso-pharynx and sinuses suggests that the infection reaches the meninges through this

route. Pneumonia, pleurisy, empyema, congestion with œdema, intracranial abscess, endocarditis (sometimes without meningitis), pericarditis and peritonitis have occurred. Councilman reports that in 13 cases there was congestion with œdema, in 7 broncho-pneumonia, in 2 characteristic croupous pneumonia with pneumococci, in 8 pneumonia due to the meningococcus.

The *spleen* varies a good deal in size. In only three of the Boston fatal cases was it much enlarged. The *liver* is rarely abnormal. *Acute nephritis* may be present. The intestines sometimes show swelling of the follicles.

Symptoms.—Cases differ remarkably in character and many different forms are described. These are perhaps best grouped into three classes:

(a) **MALIGNANT FORM.**—This fulminant type is found with variable frequency in epidemics and may occur sporadically. The onset is sudden, usually with violent chills, headache, somnolence, spasms in the muscles, great depression, moderate elevation of temperature, and feeble pulse, which may fall to 50 or 60. Usually a purpuric rash develops. In a Philadelphia case, a young girl, apparently quite well, died within twenty hours of this form. There are cases in which death has occurred within a shorter time.

(b) **ORDINARY FORM.**—The stage of incubation is probably four or five days. The disease usually sets in suddenly. There may be premonitory symptoms: headache, pains in the back, and loss of appetite. More commonly, the onset is with headache, severe chill, and vomiting. The temperature rises to 101° or 102°. The pulse is full and strong. An early and important symptom is a painful stiffness of the muscles of the neck. The headache increases and there are photophobia and great sensitiveness to noises. Children become very irritable and restless. In severe cases the contraction of the muscles of the neck sets in early, the head is drawn back, and when the muscles of the back are also involved, there is orthotonos, which is more common than opisthotonos. The pains in the back and in the limbs may be very severe. The motor symptoms are most characteristic. Tremor of the muscles may be present, with tonic or clonic spasms in the arms or legs. Rigidity of the muscles of the back or neck is very common, and the patient lies with the body stiff and the head drawn so far back that the occiput may be between the shoulder-blades. Except in early childhood convulsions are not common. Strabismus is a frequent and important symptom. Spasm or paralysis of the muscles of the face may occur. Cases have been described with such general rigidity and stiffness that the body could be moved like a statue.

The onset may be with local infection of the nose and throat with coryza, pharyngitis and tonsillitis, or conjunctivitis may occur. If there is a period of septicæmia before meningitis occurs, the patient is dull and disturbed by handling and complains of headache and general malaise with hyperæsthesia. Arthralgia or arthritis may be present.

Of sensory symptoms, headache is the most dominant and persists from the outset. It is chiefly in the back of the head, and the pain extends into the neck and back. There may be great sensitiveness along the spine, and in many cases there is general hyperæsthesia.

The *psychical* symptoms are pronounced. Delirium occurs at the onset, occasionally of a furious and maniacal kind. The patient may display marked erotic symptoms at the onset. The delirium gives place in a few days to stupor, which, as the effusion increases, deepens to coma.

Death
in 24 hrs

The temperature is irregular and variable. Remissions occur frequently, and there is no uniform or typical curve during the disease. In some instances there has been little or no fever. In others the temperature may reach 105° or 106° or, before death, 108° . The pulse may be very rapid in children; in adults it is at first usually full and strong. In some cases it is remarkably slow. Sighing respirations and Cheyne-Stokes breathing occur in some instances. Unless there is pneumonia the respirations are not often increased in frequency.

The cutaneous features are important. Herpes occurs with a frequency almost equal to that in pneumonia. The petechial rash, which has given the name "spotted fever" to the disease, is very variable. Stillé states that of 98 cases in the Philadelphia Hospital, no eruption was observed in 37. It appears to have been more frequent in the epidemics in America than in Europe. The petechiæ may be numerous and cover the entire skin. An erythema or dusky mottling may be present. In some instances there have been rose-colored hyperæmic spots like the typhoid rash. Urticaria or erythema nodosum, ecthyma, pemphigus, and in rare instances gangrene of the skin have been noted.

Leucocytosis is an early and constant feature, and ranges from 25,000 to 40,000 per cubic millimetre. It persists even in the most protracted cases. The meningococcus is present in the blood during life and has been demonstrated in the leucocytes.

Vomiting may be a special feature at the onset; as a rule, it subsides but in some instances it persists and becomes a most serious and distressing symptom. Diarrhœa is not common, the bowels being usually constipated. The abdomen is not tender. In the acute form the spleen is usually enlarged. The urine is sometimes albuminous and the quantity may be increased. Glycosuria has been noted, and hæmaturia in the malignant types.

The duration of the disease is extremely variable. Hirsch rightly states that it may range from a few hours to several months. More than half of the deaths occur within the first five days. In favorable cases, after five or six days, improvement is indicated by a lessening of the spasm, reduction of the fever, and a return of the intelligence. A sudden fall in the temperature is of bad omen. Convalescence is extremely tedious, and may be interrupted by a relapse or recrudescence, complications and sequelæ.

(c) ANOMALOUS FORMS.—(1) *Abortive Type*.—The attack sets in with great severity, but in a day or two the symptoms subside and convalescence is rapid. Strümpell distinguished between this abortive variety, which begins with such intensity, and the mild ambulant cases described by certain writers. In the mild cases, as distinguished from the abortive, the patients complain of headache, nausea, sensations of discomfort in the back and limbs, and stiffness in the neck. There is little or no fever, and only moderate vomiting. These cases could be recognized only during the prevalence of an epidemic and are easily regarded as influenza.

(2) *An intermittent type* was recognized by von Ziemssen and Stillé. It is characterized by exacerbations of fever, which may recur daily or every second day, or follow a curve of an intermittent or remittent character. The pyrexia resembles that of pyæmia rather than malaria. These are probably instances of the chronic septicæmic form.

(3) *Chronic Form*.—An attack may be protracted for from two to five or even six months, and may cause the most intense marasmus. It is characterized by a series of recurrences of the fever, and may present the most complex symptomatology. These patients show extreme emaciation, bed sores form, rigidity is marked, blindness and deafness are common, so that death comes as a welcome release. It is probable that in these protracted cases chronic hydrocephalus or abscess of the brain is present.

(4) *Posterior Basic Form*.—This occurs in young children and the early stages may show nothing peculiar. Retraction of the head is marked. Vomiting is persistent and emaciation is rapid. The course is chronic, the child lying without motion for hours, often with marked arching of the back. Lumbar puncture may give the usual findings early, but later the meningococcus disappears and it may be impossible to obtain any fluid due to the closure of the foramen. Internal hydrocephalus is marked. Death usually results in some weeks.

(5) *Chronic Septicæmic Form*.—There may be a blood infection for a considerable period, weeks or months, without meningitis as a rule. The features are headache, intermittent fever, arthritic pains or arthritis, and a rash. The patient may not seem very ill. The diagnosis is made by blood culture and is rarely possible from the clinical features.

Complications.—Pleurisy, pericarditis, and parotitis are not uncommon. The last has been associated with thyroiditis and orchitis.

Pneumonia is described as frequent in certain outbreaks. Councilman suggests that the pneumonia of the disease is not the true lobar form, but due to the meningococcus. This was found in eight of the Boston cases, and in one it was so extensive that it could have been mistaken for the ordinary lobar pneumonia. Cerebro-spinal fever sometimes prevails extensively with ordinary pneumonia, as in New York in the winter of 1903-'04. *Arthritis* has been the most frequent complication in certain epidemics. Many joints are affected simultaneously with swelling, pain, and exudation, sometimes serous, sometimes purulent. This was first observed by James Jackson, Sr., in the epidemic which he described. *Spondylitis* occurs rarely. *Enteritis* is rare. *Epididymitis* is common in some epidemics.

Hydrocephalus occurs in two forms. (1) In the *generalized* form there is an increased amount of cerebro-spinal fluid present throughout, without obstruction of the foramina. The patient has headache, stupor of some degree, vomiting and dilated pupils. Lumbar puncture should be done repeatedly and marked results support the diagnosis. (2) In *internal* hydrocephalus the foramina are closed and the symptoms are usually more marked than in the generalized form. In young children the fontanelles may bulge. Persistent vomiting, convulsions, increasing stupor, tremors, incontinence of urine and feces, and a negative lumbar puncture are suggestive. On percussion of the skull behind the junction of the frontal, parietal and temporal bones there is a tympanitic quality to the note (Macewen). In these cases puncture of the lateral ventricles is indicated. Mental feebleness and aphasia have occasionally been noted. Paralysis of individual cranial nerves or of the lower extremities may persist for some time. In some of these cases there may be peripheral neuritis, as Mills suggested. Headache may persist for months or years after an attack.

SPECIAL SENSES.—Eye.—Optic neuritis may follow involvement of the nerve in the exudation at the base. Acute papillitis was found in 6 out of 40 cases examined by Randolph. The inflammation may extend directly into the eye along the pia-arachnoid of the optic nerve, causing purulent choroido-iritis or even keratitis. A neuritis of the fifth nerve may be followed by keratitis and purulent conjunctivitis.

Ear.—Deafness often occurs early and is bilateral and permanent. It may follow inflammation of the labyrinth. Otitis media, with mastoiditis, may occur from direct extension. In 64 cases of meningitis which recovered, Moos found that 55 per cent. were deaf. He suggests that the abortive form of the disease may be responsible for many cases of early acquired deafness. In children this not infrequently leads to deafmutism.

Nose.—Coryza is not infrequent early in the disease, probably associated with the presence of the organism on the nasal mucous membrane. In carriers the organism may persist for weeks, in a small number over three months.

Diagnosis.—(a) GENERAL FEATURES.—The fever, headache, delirium, retraction of the neck, tremor, and rigidity of the muscles are most important signs. In the meningitis of cerebro-spinal fever the spinal symptoms are very much more marked than in the other forms. One has constantly to bear in mind that certain cases of typhoid fever and pneumonia closely simulate meningitis. Lumbar puncture is of great aid in recognizing the cases of meningism. Mild cases of meningitis are often mistaken for influenza.

(b) Among the SPECIAL DIAGNOSTIC FEATURES may be mentioned:

Kernig's Sign.—When the thigh is flexed at right angles to the abdomen, the leg can be extended upon the thigh nearly in a straight line. If meningeal irritation be present, strong contractures of the flexors prevent the full extension of the leg on the thigh.

Brudzinski's Sign.—Flexing the head on the chest causes flexion of the legs at the hip and knee joints, and flexing one leg on the trunk produces the same movement in the other leg.

Lumbar Puncture.—The procedure in a majority of cases can be done without general anaesthesia. The fluid runs, as a rule, with increased pressure which may reach 250-300 mm., the normal being about 120 mm., and when meningitis is present it is usually turbid, sometimes purulent, occasionally bloody. Meningitis may be present with a clear fluid. The cytology of the fluid is important. At an early stage there is an increase in the lymphocytes but usually when puncture is done the polymorphonuclear leucocytes are in great excess. In the late stages and in the posterior basic form the formula may be reversed. In the majority of cases extra- and intra-cellular meningococci are found in smears. Cultures should always be made. There is rarely any difficulty in determining between the pneumococcus and the meningococcus. If there is any doubt as to the organism the agglutination test should be done or the meningococcus searched for in the naso-pharynx. Meningitis due to the pyogenic organisms is usually easily recognized by a careful study of the cerebro-spinal fluid. A thorough search will usually show tubercle bacilli in cases of tuberculous meningitis or a guinea-pig may be inoculated.

Prognosis.—The mortality before the use of serum was about 75 per cent. In children below the age of two years the death-rate is high. A severe onset, marked coma or delirium, convulsions, high fever and hydrocephalus are of grave omen. The earlier the serum is given the better the outlook.

Prophylaxis.—The patient should be isolated, seen only by the doctor, nurses, and one or two members of the family. Cultures from the nasopharynx of those in immediate contact should be taken and carriers should be isolated until proved to be free of infection. The use of chloramin (1 per cent.) and zinc sulphate (1.5 per cent.) solution has been helpful in some cases. These may be applied directly to the mucous membrane or the chloramin used in an oil spray after thorough cleansing with saline solution. A 1 per cent. solution of peroxide of hydrogen or a solution of iodine (1 per cent.) and glycerine may be used as a spray. Some carriers prove very resistant; in others the germs disappear after a few days. Hexamine, 30 to 50 grains daily, may be given. Protective vaccination was tried extensively in the last English epidemic.

Treatment.—The patient should be kept as quiet as possible, handled gently, and all causes of irritation removed. Special attention should be given to the care of the skin owing to the danger of bedsores. The hair should be clipped close and an ice-bag applied to the head. The diet should be liquid, as concentrated as possible, and given at short intervals. If swallowing is difficult the patient can be fed through a tube. Water should be given freely. The bowels are to be opened by a calomel and saline purge, and laxatives or enemata used later if necessary. For severe headache, general pains or vomiting, morphia hypodermically is usually best. The administration of hexamine, sixty grains (4 gm.) a day, is worthy of a trial.

SERUM THERAPY.—To Flexner we owe the specific serum which has reversed the mortality and recovery rates—one of the most striking advances in modern therapy. The serum should be given as early as possible and also in doubtful cases. It should be given intravenously in severe cases with signs of septicæmia (rash or arthritis) in doses of 100 c. c. every eight hours, first desensitizing by giving 1 c. c. subcutaneously. As the bacteræmia is early and transient, later intravenous administration is not necessary. Whenever the fluid obtained by lumbar puncture is purulent the serum should be given intraspinally, but repeated only if the meningococcus is found. Before giving the serum as much cerebro-spinal fluid as possible should be withdrawn. If this has been large in amount (over 40 c. c.) and in severe cases, 45 c. c. of serum should be introduced slowly through the needle and by gravity. In ordinary cases 30 c. c. of the serum should be given. In all cases with abnormal resistance to the injection of serum after an amount equal to the fluid removed has been injected, it is well to stop. If the symptoms are very severe or increasing, the injection should be repeated in twelve hours. Otherwise the usual dose (30 c. c.) should be given daily for four days. If meningococci are found after this, daily injections should be continued. Continuance or exacerbation of the symptoms demands further injections. If the condition remains stationary after four days' interval, the four daily injections should be given again and this repeated until the organisms disappear and the symptoms abate. Injection into the cisterna magna through the atlanto-occipital ligament is sometimes more effectual. An average dosage of serum is 400-

600 c. c. intravenously and 100 c. c. intraspinally. The failure of the serum is sometimes due to its preparation from a different strain from the one infecting the patient and the need of a polyvalent serum is evident. In the chronic forms the serum should be given if organisms are present and in the posterior basic form in the hope of benefit.

HYDROTHERAPY.—This may give relief to the symptoms. Hot baths or hot packs may be given for fifteen minutes every three hours.

LUMBAR PUNCTURE.—Done for injection of the serum it is often of value in itself. Severe headache and marked cerebral features are indications. As much fluid as possible should be removed and if under high pressure early repetition is advisable. Lumbar or cisternal puncture should be done early and frequently with signs of accumulation of fluid in the ventricles.

COMPLICATIONS.—Conditions due to extension to the cranial nerves are not influenced by treatment. *Otitis* requires early incision and *arthritis* rest, local applications and incision if suppuration occurs. With signs of generalized hydrocephalus, repeated drainage with injection of serum may be tried. With internal hydrocephalus the ventricle should be punctured, fluid withdrawn and serum injected. This is readily done through the anterior fontanelle, if it is still open, the ventricle being reached at a depth of about 3 cm. In older patients a flap of bone has to be removed. In the chronic cases every effort should be made to nourish the patient well and especial precautions taken against bed-sores. For the pain and stiffness sometimes occurring in convalescence, hot baths and massage are useful.

X. INFLUENZA (LA GRIPPE)

Definition.—An acute infectious disease, which is pandemic, epidemic and endemic. The pandemics occur irregularly about three to a century and are characterized by a remarkable rapidity of extension and the large number attacked. Following the pandemic there are, as a rule, for several years endemic, epidemic, or sporadic outbreaks in different regions. Clinically, the disease has protean aspects, but a special tendency to attack the respiratory mucous membranes. A special organism, *Bacillus influenzae*, is found. There is no agreement that it is the specific cause of the disease and in any case secondary infection with other organisms is common.

History.—Great pandemics have been recognized since the sixteenth century. There were four with their succeeding epidemics during the last century—1830-'33, 1836-'37, 1847-'48, and 1889-'90. The last seems to have begun, as many others, in the Far East. The pandemic of 1918 far exceeded any of its predecessors in its intensity. It is unusual to have the culmination in the summer months as was the case in some countries. A special feature was the high mortality in young adults, the very young and the old being comparatively immune. The accompanying pneumonia was very virulent. Pregnant women seemed particularly susceptible. The epidemic was severe in the American camps and on the transports. The *Olympic* arrived in port with 5,951 troops. On the day of arrival 571 cases of acute respiratory disease developed and within three weeks there were 1,668 cases. Of these, 534 (32 per cent.) had pneumonia, of whom 317 died (59 per cent.).

The duration of an epidemic in a locality is from six to eight weeks. With the exception, perhaps, of dengue, there is no disease which attacks indiscriminately so large a portion of the inhabitants, about 40 per cent., as a rule. Fortunately, the rate of mortality is low if all cases are included.

Etiology.—What relation has the epidemic influenza to the ordinary influenza cold or catarrhal fever (commonly also called the *grippe*), which is constantly present in the community? Leichtenstern answers this question by making the following divisions: (a) *Epidemic influenza vera*; (b) *endemic-epidemic influenza vera*, which often occurs for several years in succession after a pandemic; (c) *endemic influenza nostras*, pseudo-influenza or catarrhal fever, commonly called the *grippe*, is caused by various organisms, alone or in combination, and bears the same relation to the true influenza as cholera nostras does to Asiatic cholera.

Since the pandemic of 1889-'90 we have not been free from local outbreaks in some part of the world. In some places the disease seems to have been continually present. The reports are sufficiently numerous to show that the influenza bacillus is constantly with us. Many observations show that it is a frequent invader of the respiratory tract in the inter-epidemic periods and is probably responsible for many of the cases of *influenza nostras*. It seems to bear a similar relation to the acute infections of the respiratory tract as other common organisms. We do not know what determines the sudden increase in virulence which characterizes the pandemics. During the pandemics and the subsequent epidemic outbreaks the disease assumes a severity quite different from that of the inter-epidemic disease. The outstanding features are not the same in the pandemics; in that of 1889-'90 the nervous system was specially attacked, in 1918 the respiratory tract. The student must remember that descriptions of the severe epidemic cases do not apply to the usual endemic form.

The disease is highly infectious; it spreads with remarkable rapidity, which, however, is not greater than modern methods of conveyance. In the great pandemics some of the large prisons escaped entirely. The outbreak of epidemics is independent of all seasonal and meteorological conditions. One attack does not necessarily protect from a subsequent one.

Pathology.—As death results usually from broncho-pneumonia this is the usual finding at autopsy. The lesions vary with the predominating organism, thus in 1918 in the United States many cases of pneumonia were associated with the *Streptococcus hæmolyticus*. When the *B. influenzae* predominates there may be acute peri-bronchial infiltration with marked hæmorrhage and œdema. There is primarily injury of and desquamation of the epithelium with distention of the alveoli and rupture with hæmorrhage into the air spaces. A hyaline membrane is formed with hyaline degeneration in the terminal bronchioles. There is a severe tracheitis and bronchitis, often hæmorrhagic. Hæmorrhage, œdema and acute emphysema were marked features in the 1918 epidemic.

Bacteriology.—In 1892 Pfeiffer isolated a bacillus from the nasal and bronchial secretions, which by some is recognized as the cause of the disease. It is a small, non-motile organism, which stains well in Loeffler's methylene blue, or in a dilute, pale-red solution of carbolfuchsin in water. It has been found in the blood in a number of cases. The bacilli are present in enormous

numbers in the nasal and bronchial secretions, in the latter almost in pure culture. They persist often after the severe symptoms have subsided. The experience of the pandemic of 1918 raised the question as to the relation of the influenza bacillus to the disease. Is it the responsible organism or a secondary invader? The evidence is conflicting but does not seem to justify the conclusion that this organism is not causal. There are many secondary invading organisms, which vary in character in different localities. Olitsky and Gates found an organism, *B. pneumosintes*, which causes antibody formation in inoculated animals and humans; other organisms have been suggested.

Symptoms.—The incubation period is from one to four days and has an average of two days. The onset is usually abrupt, with fever and its associated phenomena, headache, general pains, prostration and sometimes sore throat and an irritating cough.

Forms of the Disease.—The manifestations are so extraordinarily complex that it is best to describe them under various headings.

(a) **RESPIRATORY FORM.**—The mucous membrane of the respiratory tract from the nose to the air cells of the lungs may be regarded as the seat of election of the infection. In the simple forms the disease sets in with coryza, and presents the features of an acute catarrhal fever, with perhaps rather more prostration and debility than is usual. In other cases after catarrhal symptoms tracheitis and bronchitis occur, the fever increases, there is delirium and much prostration, and the picture is that of severe toxæmia. The cough is usually very severe and persistent. Edema of the larynx was not uncommon in the 1918 epidemic. The graver respiratory conditions are bronchitis, pleurisy, and pneumonia. The bronchitis has really no special peculiarities but the sputum is supposed by many to be distinctive. Sometimes it is in extraordinary amounts, very thin, and containing purulent masses. Pfeiffer regards sputum of a greenish-yellow color and in coin-like lumps as almost characteristic of influenza. In other cases there may be a bright or dark red, bloody sputum. The process tends to go on to broncho-pneumonia.

Influenza pneumonia is one of the most serious manifestations, and may depend upon Pfeiffer's bacillus itself or a secondary infection. The true influenza pneumonia is lobular and probably never lobar. It was a special feature of the 1918 pandemic and responsible for most of the deaths. It may be present from the onset or develop after some days of general infection. The signs were often atypical for several days and suppression of breath-sounds and fine crackling râles were the common early signs. Severe cough with bloody sputum or hæmoptysis is common. Cyanosis is usually marked. There is a special tendency to the secretion of fluid so that the lungs are "water-logged." Abscess or gangrene follows not infrequently. The toxæmia is often extreme but the circulation shows remarkably little change in many cases. The blood pressure is usually low. Subcutaneous emphysema was common in the 1918 epidemic, usually over the neck and upper thorax but sometimes very widespread. In many of these cases there was extreme emphysema of the lungs. Probably the air escaped, after rupture of a surface bleb, into the mediastinum and then reached the tissues of the neck.

Influenza pleurisy is more rare, but cases of primary involvement of the pleura are reported. It is very apt to lead to empyema. Pulmonary tuberculosis is usually aggravated by an attack of influenza.

(b) NERVOUS FORM.—Without any catarrhal symptoms there are severe headache, pain in the back and joints, with profound prostration. Among the more serious complications may be mentioned meningitis and encephalitis, the latter leading to hemiplegia or monoplegia. Abscess of the brain has followed in acute cases. Myelitis, with symptoms like an acute Landry's paralysis, has occurred, and spastic paraplegia or a pseudo-tabes may follow an attack. In the 1918 epidemic there were cases of widespread hæmorrhage into the spinal thecæ. The influenza bacillus has been demonstrated by lumbar puncture during life and in the meninges after death. All forms of neuritis are not uncommon, and in some cases are characterized by marked disturbance of motion and sensation. Judging from the accounts in the literature, almost every form of disease of the nervous system may follow influenza. Among the most important of the nervous sequelæ are depression, melancholia, and in some cases dementia.

(c) GASTRO-INTESTINAL FORM.—With the onset of the fever there may be nausea and vomiting, or the attack may set in with abdominal pain, profuse diarrhœa, and collapse. In some epidemics jaundice has been a common symptom. In a considerable number of the cases there is enlargement of the spleen, depending chiefly upon the intensity of the attack.

(d) FEBRILE FORM.—The fever in influenza is very variable, but it is important to recognize that it may be the only manifestation of the disease. It is sometimes markedly remittent, with chills; or in rare cases there is a protracted, continued fever of several weeks' duration, which simulates typhoid closely. Sometimes the fever resembles that of a tertian malaria.

Blood.—*Leucopenia* is the rule, sometimes with an increase in the lymphocytes and decrease or absence of the eosinophiles. Complications may cause a leucocytosis but in the 1918 epidemic leucopenia often persisted through a broncho-pneumonia.

Complications.—*Pericarditis* is apt to be latent. Of *endocarditis*, cases have been reported in which micro-organisms morphologically like influenza bacilli have been isolated from the vegetations. The malignant form may occur. *Myocarditis* may follow, and has been a cause of sudden death. Functional disturbances are common, palpitation, bradycardia, tachycardia, and angina-like attacks. *Phlebitis* and *thrombosis* of various vessels have been described. *Meningitis* occurs occasionally. Rivers (1922) collected 220 cases, 80 per cent. of which were under two years of age. The mortality was 92 per cent. *Peritonitis* is rare. *Cholelithiasis* may follow an attack.

Various renal affections have been noted, but *nephritis* was rare in the 1918 pandemic. *Orchitis* has been seen. *Herpes* is common. A diffuse erythema sometimes occurs, occasionally purpura. *Catarrhal conjunctivitis* is a frequent event. *Iritis*, and in rare instances *optic neuritis*, have been met with. *Acute otitis media* is a common complication and infection of the sinuses is not rare. Severe and persistent *vertigo* may follow influenza, probably from involvement of the labyrinth. *Bronchiectasis* is a not uncommon sequel and the sputum may contain influenza bacilli in large numbers.

Since the late severe epidemics it has been the fashion to date various ailments of chronic ill health from influenza. In many cases this is correct. It is astonishing how many people have been crippled in health after an attack,

particularly with bronchial, nervous or circulatory disturbances. *Alopecia* sometimes follows but is rarely permanent.

Diagnosis.—During a pandemic the cases offer but slight difficulty. The profoundness of the prostration, out of all proportion to the intensity of the disease, is one of the most characteristic features. The diagnosis of gastrointestinal influenza should be made with caution, except in pandemics. “In-
testinal influenza” is usually a cover for ignorance. The more chronic pulmonary infections are sometimes mistaken for tuberculosis. The differentiation of the various forms has been sufficiently considered. The diagnosis of influenza is often made carelessly in various forms of coryza and respiratory tract infection.

Prognosis.—In epidemics the outlook depends largely on the existence of broncho-pneumonia. At other times age is important; in the very young and the aged, especially if debilitated, the danger is greater.

Treatment.—Isolation should be practised when possible, and old people should be guarded against all possible sources of infection. There is no conclusive proof that vaccines have a preventive effect or that they are useful in treatment. The secretions, nasal and bronchial, should be thoroughly disinfected. In every case the disease should be regarded as serious, and the patient confined to bed at once and for some days after the fever has disappeared, as relapse is common. In this way serious complications may be avoided. From the onset the treatment should be supporting, and the patient carefully fed and well nursed. Water should be given freely. The bowels should be opened by a dose of calomel or a saline draught. At night 10 grains (0.65 gm.) of Dover’s powder may be given. At the onset a warm bath is sometimes grateful in relieving the pain in the back and limbs, but great care should be taken to have the bed well warmed, and the patient should be given a hot drink after it. The patient should be sponged several times a day, and an ice-bag applied to the head. If the fever is high or there is much discomfort, acetyl-salicylic acid (gr. x, 0.6 gm.) may be given. The medicinal antipyretics should be used with caution, as profound prostration sometimes occurs after their employment. An alkali, such as potassium citrate (gr. xv, 1 gm.) four times a day, should be given. Too much stress should not be laid upon the mental features. Delirium may be marked even with slight fever. In the cases with cardiac weakness stimulants should be given freely, and during convalescence strychnia in full doses.

The intense bronchitis, pneumonia, and other complications should receive their appropriate treatment. The convalescence requires careful management, and it may be weeks or months before the patient is restored to full health. A good nutritious diet, change of air, and pleasant surroundings are essential. The depression following this disease is one of its most unpleasant and obstinate features.

XI. WHOOPING COUGH

Definition.—A specific affection due to the *Bacillus pertussis*, characterized by catarrh of the respiratory passages and a series of convulsive coughs which end in a long-drawn inspiration or “whoop.”

History.—Ballonius, in his *Ephemerides*, describes the disease as it appeared in 1578. Glisson and Sydenham in the following century gave brief accounts. Willis (*Pharmaceutice Rationalis*, second part, 1674) gave a much better description and called it an "epidemic disorder."

Etiology.—The disease occurs in epidemic form, but sporadic cases appear in a community from time to time. It is directly infectious from person to person; but rooms, houses, school-rooms, and other localities may be infected by a sick child. It is, however, in this way less infectious than other diseases, and is probably most often conveyed by direct contact. Epidemics prevail for two or three months, usually during the winter and spring, and have a curious relation to other diseases, often preceding or following epidemics of measles, less frequently of scarlet fever.

Children from one to ten years of age are most liable to be attacked. Sucklings are not exempt, and there may be very severe attacks in infants under six weeks. Congenital cases are described. It is stated that girls are more subject to the disease than boys. Adults and old people are sometimes attacked, and in the aged it may be a very serious affection. It appears to be most infectious in the catarrhal period. A natural immunity has been mentioned, but it must be remembered that a child may have the disease in a very mild form and as a rule, one attack protects. The disease is more than twice as fatal in the negro race as in others. There were 2,976 deaths from it in 1928 in England and Wales.

The *Bacillus pertussis* is found in early stages of the disease (in 75 per cent. during the catarrhal stage) but not often after the third week of the paroxysmal stage. In convalescents the deviation of complement reaction is present and the serum agglutinates the organism. The complement fixation test is not given early and so is not of great value in diagnosis. Apes have been successfully inoculated.

Morbid Anatomy.—Whooping cough itself has no special pathological changes. In fatal cases pulmonary complications, particularly bronchopneumonia, are usually present. Collapse and compensatory emphysema, vesicular and interstitial, are found, and the tracheal and bronchial glands are enlarged.—There is a constant lesion of the trachea with the presence of bacilli between the columnar cells.

Symptoms.—The incubation period is difficult to give exactly and extremes of four to twenty days are given; probably ten days is a fair average. Catarrhal and paroxysmal stages can be recognized. In the catarrhal stage the child has the symptoms of an ordinary cold, which may begin with slight fever, running at the nose, injection of the eyes, and a bronchial cough, usually dry, and sometimes giving indications of a spasmodic character. Trousseau called attention to the incessant character of the early cough. The fever is usually not high and the symptoms may be thought to be those of a simple catarrh. After a week or ten days, instead of subsiding, the cough becomes worse and more convulsive in character. Paroxysmal sneezing may take the place of the cough.

The paroxysmal stage, marked by the characteristic cough, dates from the first appearance of the "whoop." The fit begins with a series of from fifteen to twenty forcible short coughs of increasing intensity, between which no inspiratory effort is made. The child gets blue in the face, and then with a deep

inspiration the air is drawn into the lungs, making the "whoop," which may be heard at a distance, and from which the disease takes its name. A deep inspiration may precede the series of spasmodic expiratory efforts. Several coughing fits may succeed each other until a tenacious mucus is ejected, usually small in amount, but after a series of coughing spells a considerable quantity may be expectorated. Vomiting often takes place at the end of a paroxysm, and may recur so frequently that the child does not get enough food and becomes emaciated. There may be only four or five attacks in the day; an average is twenty attacks daily. They may be more frequent and severe at night. In severe and fatal cases the paroxysms may exceed one hundred daily. During the paroxysm the thorax is strongly compressed by the powerful expiratory efforts, and, as very little air passes in, there are signs of defective aëration of the blood; the face becomes swollen and congested, the veins are prominent, the eyeballs protrude, and the conjunctivæ become deeply engorged. Suffocation indeed seems imminent, when with a deep, crowing inspiration air enters the lungs and the color is quickly restored. The child knows for a few moments when the attack is coming on, and tries in every way to check it, but failing to do so, runs terrified to the nurse or mother to be supported, or clutches anything near by. Few diseases are more painful to witness. In severe paroxysms the sphincters may be opened. An ulcer may form under the tongue from rubbing on the teeth (Riga's disease). Among circumstances which precipitate a paroxysm are emotion, such as crying, and any irritation in the throat. Even the act of swallowing sometimes seems sufficient. In a close dusty atmosphere the coughing fits are more frequent. After lasting for three or four weeks the attacks become lighter and finally cease. In cases of ordinary severity the course of the disease is rarely under six weeks.

During the attack, if the chest be examined, the resonance is defective in the expiratory stage, full and clear during the deep, crowing inspiration; but on auscultation during the latter there may be no vesicular murmur heard, owing to the slowness with which the air passes the narrowed glottis. Bronchial râles are occasionally heard.

Blood.—There is usually a marked leucocytosis (15,000-25,000) which may appear early. There is generally a marked increase in the lymphocytes and myelocytes may be found.

Complications and Sequelæ.—During the extensive venous congestion hæmorrhages are very apt to occur in the form of petechiæ, particularly about the forehead, ecchymosis of the conjunctivæ, and even tears of blood (Trousseau) from the rupture of the vessels, epistaxis, bleeding from the ears, and occasionally hæmoptysis. Hæmorrhage from the bowels is rare. Glycosuria occurs occasionally. Convulsions are not very uncommon, due perhaps to the extreme engorgement of the cerebral cortex. Death has occurred from spasm of the glottis. Sudden death has been caused by extensive subdural hæmorrhage. Choked disk, relieved by decompression, has occurred. Arthritis occurs occasionally. Paralysis is a rare event. It was associated with 3 in a series of 120 cases, but in none of them did the hemiplegia come on during the paroxysm, as in a case reported by S. West. Valentine (1901) collected 79 cases, chiefly hemiplegias. A spastic paraplegia may follow. Acute polyneuritis is a rare sequel. Otitis media is not uncommon.

The pulmonary complications are extremely serious. During the severe coughing spells interstitial emphysema may be induced, more rarely pneumothorax. Occasionally the air reaches the subcutaneous tissues of the neck, and the condition may become general. Capillary bronchitis and bronchopneumonia are the dangerous complications, responsible for nine out of ten deaths in the disease. In some cases the process is tuberculous. Pleurisy is sometimes met with and occasionally lobar pneumonia. Enlargement of the bronchial glands is very common in whooping cough, and has been thought to cause the disease. During the spasm the radial pulse is small, the right heart engorged, and during and after the attack the cardiac action is disturbed. It is doubtful if serious damage results, or if valvular disease in children can be attributed to whooping cough. Koplik regarded the swelling about the face and eyes as an important sign of heart strain. Serious renal complications are very uncommon, but albumin sometimes and sugar frequently are found in the urine. A distressing sequel in adults is asthma, which may recur at intervals for a year or more. Bronchiectasis is an occasional sequel. A paroxysmal cough may persist for months after an attack, especially in adults.

Diagnosis.—A persistent paroxysmal cough, without sufficient signs to explain it, should excite suspicion. When the “whoop” occurs the diagnosis is easy; but there are doubtful cases, particularly during epidemics, in which a series of expiratory coughs occurs without any “whoop.” The spasmodic cough due to enlarged bronchial glands may cause difficulty. The earlier that cultures are made, the more likely are positive results.

Prognosis.—If we include its complications, whooping cough is a very fatal affection, ranking high among the acute infections as a cause of death in children under five years of age and especially in the first year.

Prophylaxis.—The patient should be isolated and when possible the sputum should be collected and disinfected. As the organism usually disappears within four weeks from the appearance of the characteristic cough there seems little danger of infection in the later stages. A prophylactic vaccine has been used with success, three injections of 500 million, 2 and 3 billion, being given every third day.

Treatment.—The gravity of the disease is scarcely appreciated by the public. Children with the disease should not be sent to school or exposed in public in any way. There is more reprehensible neglect in connection with this than with any other disease. The patient should be in bed if the paroxysms are severe or there is fever. Fresh air, night and day, is important, but in cities in the winter this is not easy to manage. Stock vaccine has been used for treatment with benefit early in the attack; some patients are promptly cured. The average initial dose is 500 million for children over one year. With two-day intervals doses of 1 and 2 billion are given. Treatment by X-ray exposures is sometimes successful. Treatments are given every second day to a total of three; a second similar course is given after seven days in severe cases. Ephedrine hydrochloride may be useful in doses of gr. $\frac{1}{12}$ (gm. 0.005) for children under one year and gr. $\frac{1}{6}$ (gm. 0.01) for older children, given in the evening or two or three times a day. The use of benzoin and eucalyptus inhalations is often helpful. Sedatives are by far the most trustworthy drugs in severe cases, and paregoric may be given freely, particularly

to give rest at night. Codein and heroin in doses proper for the age often give much relief. Antipyrin and chloral hydrate may be tried. Chloretone may be used in doses of gr. 1 (0.065 gm.) four times a day for a young child. Benzyl benzoate (5 to 30 drops of the 20 per cent. solution) is sometimes useful and also painting the throat with a 2 per cent. solution of silver nitrate. Children can often be taught to inhibit an attack. The wearing of a tight abdominal binder is sometimes of value. If vomiting is severe it is well to give food in small amounts immediately after the paroxysm.

After the severity of the attack has passed and convalescence has begun, the child should be watched with the greatest care. It is at this period that broncho-pneumonia is apt to develop. The cough sometimes persists for months and the child remains weak and delicate. Change of air should be tried. Such a patient should be fed with care and given tonics and cod-liver oil.

XII. GONOCOCCUS INFECTION

Definition.—An acute infection with a primary lesion, usually urethritis, and numerous secondary and systemic manifestations, of which prostatitis and epididymitis, salpingitis, arthritis, synovitis and endocarditis are the most important. The *Micrococcus gonorrhææ* (gonococcus) was described by Neisser, in 1879.

Gonorrhœa, a widespread and serious disease, presents many features for consideration. It is not a killing disease; 76 fatal cases are recorded in 1928, for England and Wales, and 955 in the U. S. registration area in 1925, but as a cause of ill-health and disability the gonococcus occupies a position of the very first rank among its fellows. While the local lesion is too often thought to be trifling, in its singular obstinacy, in the possibilities of permanent sexual damage to the individual himself and still more in the "grisly troop" which may follow in its train, gonorrhœa does not fall very far short of syphilis in importance.

Etiology.—The organism is a biscuit-shaped micrococcus, occurring in pairs, usually within the leucocytes, and is always found in the primary and systemic lesions. Two types of gonococci are described, corresponding to the adult and infant forms of infection. The disease has been reproduced by inoculation of the pure culture.

The disease occurs as a result of impure sexual intercourse, in the newborn from vaginal contamination, and in older children by accidental infection. Ophthalmia neonatorum is one of the great causes of blindness, but an active campaign of education is rapidly reducing the number of cases. The gonococcus vaginitis and the ophthalmia are very serious diseases in children's hospitals and in infants' homes. The story of the gonococcus infection in the Babies' Hospital, New York, for eleven years, as told by Holt (N. Y. Med. Jour., March, 1905), illustrates its singular obstinacy. In spite of the greatest care and precaution, there were, in 1903, 65 cases of vaginitis, with 2 of ophthalmia and 12 of arthritis. In 1904 there were 52 cases of vaginitis, only 16 of which would have been recognized without the bacteriological examination. In all, in eleven years, there were 273 cases of vaginitis, only 6 with ophthalmia and 26 with arthritis. Other institutions have had equally

sad experiences. Isolation and prolonged quarantine are the only measures to combat the disease successfully.

The effects of the gonococcus may be considered under:

I. The primary infection.

II. The spread in the genito-urinary organs by direct continuity.

III. Systemic gonococcus infection.

The primary lesion we need not here consider, but we may call attention to the frequency of the complications, such as periurethral abscess, gonorrhœal prostatitis and seminal vesiculitis in the male, and vaginitis, endocervicitis, and inflammation of the glands of Bartholin in the female.

Serious sequels result from the *spread* by direct continuity of tissue. Gonococcus salpingitis is not infrequent. Metritis and ovaritis are also met with, and peritonitis. The gonococcus has been found in pure culture in cases of acute general peritonitis. Equally important is the cystitis, which is probably more frequently the result of a mixed infection than due to the gonococcus itself. There is some danger of extension to the kidneys. The pyelitis, like the cystitis, is usually a mixed infection.

Systemic Gonococcus Infection.—(1) GONOCOCCUS SEPTICÆMIA AND PYÆMIA.—Thayer and Blumer first cultivated the gonococci from the blood of a patient in Osler's wards. Of 29 cases in which septicæmia was demonstrated by positive blood cultures, 12 died. Cole divided the cases into four groups: (1) Those with endocarditis, 11 of the 29 cases collected by him. The clinical features are those of malignant endocarditis; two recovered. (2) Cases with local suppuration and the general features of a pyæmia—of the six cases three died. The septicæmia associated with a small focus of suppuration may be very intense. A man ten days after the onset of urethritis had chills and high fever; he became profoundly toxæmic and died on the morning of the fourth day from the chill. There was a small prostatic abscess. (3) Cases with no metastatic local affections or perhaps only slight arthritis. In a remarkable case at the Johns Hopkins Hospital, three months after an acute gonorrhœa the patient had a fever resembling typhoid, which lasted seven weeks. Gonococci were cultivated from the blood. (4) Cases of gonorrhœal puerperal septicæmia. In gonococcus endocarditis the aortic valve is frequently attacked and the right heart is involved more often than in endocarditis due to other organisms. Embolic phenomena may occur.

(2) GONOCOCCUS ARTHRITIS.—In many respects this is the most damaging and disabling of all the complications of gonorrhœa, occurring in from 2 to 5 per cent. of the cases. It occurs more frequently in males than in females; 43 to 7 in one series at the Johns Hopkins Hospital (Cole). Of 252 cases collected by Northrup, 230 were in males; 130 cases were between twenty and thirty years of age. It occurs, as a rule, during an acute attack of gonorrhœa. In 208 of Northrup's series there was a urethral discharge while in hospital. It may occur as the attack subsides or even when it has become chronic. A gonorrhœal arthritis of great intensity may occur in a newly married woman infected by an old gleet in her husband. In women it is not always easy to find evidence of local infection. As a rule, many joints are affected. In an analysis by Cole and McCrae of the involvement of the joints in gonococcus arthritis and in rheumatic fever, the average number in the former was double that in the latter. In Northrup's

series three or more joints were affected in 175 cases.

The *anatomical changes* are variable. The inflammation is often peri-articular, and extends along the sheaths of the tendons. When effusion occurs in the joints it rarely becomes purulent. It has more commonly the characters of a synovitis. About the wrist and hand suppuration sometimes occurs in the sheaths. The gonococcus is present in the inflamed joint or in the peri-arthritis exudate, and may be obtained in pure culture. Sometimes the cultures are negative. Mixed infection is very rare.

Clinical Course.—Variability and obstinacy are the two most distinguishing features. The following are the most important clinical forms:

(a) *Arthralgic*, in which there are wandering pains about the joints, without redness or swelling. These persist for a long time.

(b) *Polyarthritic.* The fever is usually slight; the local inflammation may fix itself in one joint, but less commonly several become swollen and tender. In this form cerebral and cardiac complications may occur. In other cases one joint is especially involved, the others subsiding rapidly. The pain is severe, the swelling extensive, due chiefly to peri-articular oedema, and synovitis is often marked. The general fever is not at all proportionate to the intensity of the local signs. The exudate usually resolves, though suppuration occasionally supervenes. Ankylosis may occur.

(c) *Chronic Hydrarthrosis.*—This is usually mono-articular, and is particularly apt to involve the knee. It comes on often without pain, redness, or swelling. Formation of pus is rare.

(d) *Bursal and Synovial Form.*—This attacks chiefly the tendons and their sheaths and the bursæ and the periosteum. The articulations may not be affected. The bursæ of the patella, the olecranon, and the tendo Achillis are most apt to be involved.

(e) *Spondylitis.*—This may be due to gonococcus infection and is usually in the lower spine. It presents no special peculiarities.

(f) *Painful Heel.*—This is due to local periosteal thickening and exostosis on the os calcis, causing pain and great disability. Baer has demonstrated the gonococcus in the periosteal lesion.

Complications.—Lritis is not infrequent and may recur with successive attacks. Meningitis, myelitis and true neuritis occur rarely. Endocarditis, pericarditis, phlebitis and pleurisy may occur. *Scitica* is fairly common, usually secondary to spondylitis or prostatitis, although a toxic factor has been suggested. Myositis and a variety of skin conditions occur especially hyperkeratosis of the palms and soles.

Diagnosis.—The thought of the possibility of gonococcus infection and a search for the primary lesion are the best safeguards. The usual error is to mistake an acute gonococcus polyarthrititis for rheumatic fever. The persistence, usually in one or two joints, and the occurrence of changes in the joints should make the diagnosis clear. The swelling often extends more above and below the joint than in other forms of arthritis. The complement fixation test is sometimes of value.

Treatment.—The primary infection—usually urethritis—should be actively treated. Of special measures, the use of foreign protein injection and vaccine treatment are worthy of trial; either helps some cases, both fail in many. Good food, fresh air, and open bowels are important. Drugs are of little

value, but the syrup of ferrous iodide (℥ i, 4 c. c.) is sometimes useful. Phenacetine or acetyl-salicylic acid may be given for the pain.

The local treatment is very important. In acute cases, fixation of the joints for a short period is beneficial, and in the chronic forms, massage and passive motion. Counter-irritation by the cautery or blisters and active hyperæmia are useful. A distended joint may be tapped and then tightly bandaged or air introduced. The surgical treatment is more satisfactory in severe cases and good results usually follow incision and irrigation.

XIII. BACILLARY DYSENTERY

Definition.—A form of intestinal flux, usually of an acute type, occurring sporadically and in severe epidemics, attacking children as well as adults, characterized by pain, frequent passages of blood and mucus, and due to the action of a specific bacillus, of which there are various strains.

Etiology.—Owing to improved sanitation, dysentery has become less frequent. In temperate climates sporadic cases occur from time to time, and at intervals epidemics prevail, particularly in overcrowded institutions. Records of widespread epidemics have been collected by Woodward. The most serious was that which prevailed from 1847 to 1856. In Great Britain and Ireland epidemics have become less frequent. In institutions, particularly in overcrowded asylums, dysentery is common. In the tropics "dysentery is a destructive giant compared to which strong drink is a mere phantom" (Macgregor). Dysentery is one of the great camp diseases, and it has been more destructive to armies than powder and shot. In the Federal service during the Civil War, according to Woodward,¹ there were 259,071 cases of acute and 28,451 cases of chronic dysentery. A very fatal form of dysentery has prevailed in Japan, with a mortality of from 26 to 27 per cent. Severe epidemics of acute dysentery are usually of the bacillary type. It is a mistake to regard bacillary dysentery as a tropical disease only; it is not uncommon in temperate zones.

BACILLUS DYSENTERIÆ.—There are two groups of dysentery bacilli. The first was discovered by Shiga in 1898 in Japan and the second by Flexner in Manila. The organisms belonging to the first group are identical, but there are several varieties of the Flexner group which react more or less to a serum prepared from any one. This immune serum has little effect on the Shiga group and vice versa. In general, infection with the Shiga group is more severe than with the other forms. The Shiga bacilli form two toxins, exotoxin and endotoxin; the Flexner bacilli endotoxin only. The organism appears to be constantly present in the acute dysentery of the tropics. In Manila, according to Strong and Musgrave, of 1,328 cases, 712 were of the acute specific variety, 55 suspected specific cases, and 561 of amœbic dysentery. Kruse, in an outbreak in Germany, isolated an identical bacillus. Vedder and Duval demonstrated that sporadic cases in adults in Philadelphia, as well as epidemics of dysentery in the Lancaster County Asylum, Pa., and in the alms-

¹ Medical and Surgical History of the War of the Rebellion, Medical, vol. ii. The most exhaustive treatise extant on intestinal fluxes—an enduring monument to the industry and ability of the author.

house at New Haven, were due to this organism. Duval and Bassett demonstrated that certain forms of summer diarrhœas of infants were due to infection with *B. dysenteriae*. The Rockefeller Institute conducted a collective investigation into the cause of infantile diarrhœas; several observers, under Flexner's direction, studied 412 cases and found the dysentery bacillus present in 279 or 63.2 per cent.

The strain of the bacillus most frequently found in the United States is the "Flexner-Harris" type. A number of strains of the bacillus occur, determined by the relative agglutinative power of immune serum upon the bacilli isolated, as well as by the action of the latter upon various sugars. The lesions produced by the different strains are identical. The organism agglutinates with the blood serum of cases with acute dysentery as well as with the serum of immunized animals. It is rarely found in the blood.

Infection takes place by the mouth. The organisms are widely distributed by the fæces of persons suffering with the disease and also by dysentery "carriers." In institutions food and drink readily become contaminated. Possibly, too, the germs are distributed by flies and dust.

Morbid Anatomy.—In the acute cases, when death has occurred on the fourth to the seventh day, the mucous membrane of the large intestine is swollen, of a deep-red color, and presents elevated, coarse corrugations and folds. In addition to the intense hyperæmia there are hæmorrhagic areas. Over the surface there is usually a superficial necrotic layer, which may be in patches, or uniform over large areas. Following the necrosis there is superficial ulceration but the edges are not undermined as in amœbic dysentery. In cases of great intensity the colon may be stiff and thick and the mucous membrane enormously increased in thickness, grayish black, extensively necrotic, and, in places, gangrenous. The serous surface is often deeply injected. The ileum may be involved, having a deeply hæmorrhagic mucosa, with a superficial necrosis.

Symptoms.—According to Strong and Musgrave, the period of incubation is not more than forty-eight hours. The onset, which is usually sudden, is characterized by slight fever, pain in the abdomen, and frequent stools. At first mucus is passed, but within twenty-four hours blood appears with it, or there is pure blood. There is a constant desire to go to stool, with great straining and tenesmus; every hour or half hour there may be a small amount of blood and mucus passed. The temperature rises and may reach 103° or 104°. The pulse increases in frequency, and in the severer cases becomes very small. The tongue is coated with a white fur, and there is excessive thirst. Vomiting may occur. In the very acute cases the patient becomes seriously ill within forty-eight hours, the movements increase in frequency, the pain is of great intensity, the patient becomes toxic and delirious, and death may occur on the third or fourth day. In cases of moderate severity the urgency of the symptoms abates, the stools lessen, the temperature falls, and within two or three weeks the patient is convalescent. The mortality in the severe forms is very high. There is a subacute form which lasts for many weeks or months. The patients become greatly emaciated, having from three to five stools in the twenty-four hours. The *B. dysenteriae* is found in the stools, and it agglutinates readily with the blood serum.

The foregoing account describes the essential features of bacillary dysen-

tery as seen in Japan and the tropics. The clinical features of bacillary dysentery in adults in temperate climates differ in no essential manner from those already described. Although the evidence hardly warrants us at present in making the sweeping statement that all non-amœbic cases of dysentery are bacillary in origin yet probably this is the case. What is known as acute catarrhal dysentery is probably a sporadic form due to the *B. dysenteriae*. Diphtheritic dysentery is a type of the bacillary form with great necrosis and infiltration of the mucosa. There may be rapid gangrene and a fatal termination within twenty-four hours. A secondary dysentery is a common terminal event in many acute and chronic diseases. In young children the disease is usually serious. There may be high fever with vomiting and rapid loss of weight. The persistent occurrence of stools containing blood or pus, or both, in infants suggests bacillary dysentery.

Chronic Form.—The acute form may gradually pass into this or the patient may have recovered apparently and relapses occur with a transition to the chronic form. There may be four to eight stools a day with blood and mucus. The general health suffers and emaciation is marked, but some patients live for many years and have a fair measure of health. The mucous membrane is inflamed and œdematous with shallow ulcers. Before a diagnosis of chronic dysentery is made care should be taken to exclude chronic poisoning and syphilis or carcinoma of the rectum. The same methods are indicated as in the diagnosis of acute dysentery.

Complications and Sequelæ.—*Peritonitis* is rare, due either to extension through the wall of the bowel or to perforation. When this occurs about the cæcal region, perityphlitis results; when low down in the rectum, periproctitis. In 108 autopsies collected by Woodward perforation occurred in 11. Abscess of the liver, so common in the amœbic form, is very rare. It is interesting to note, as illustrating the probable type of the disease, how comparatively rare abscess of the liver was during the American Civil War. Very few cases occurred in the South African War (Rolleston). Hæmorrhage from the bowel sometimes occurs and is occasionally profuse. In the tropics malaria and acute dysentery often coexist.

Sydenham noted that dysentery was sometimes associated with arthritic pains, and in certain epidemics *arthritis* has occurred. In severe cases there may be parotitis, pleurisy, thrombosis, pericarditis, endocarditis, and occasionally pyæmic manifestations, among which is pyelphlebitis. Chronic nephritis is an occasional sequel. In protracted cases there may be an anæmic œdema. An interesting sequel is paralysis of which Woodward reported 8 cases. Weir Mitchell mentioned it as not uncommon, occurring chiefly in the form of paraplegia. As in other acute fevers, this is due probably to a neuritis. Remlinger, in two cases of non-amœbic dysentery in Tunis, observed an epididymitis during convalescence; gonorrhœa was excluded. In a third case the dysentery was complicated by an abscess of the spleen, which ruptured, causing death. Intestinal stricture is a rare sequence—so rare that no case was reported at the Surgeon-General's office during the Civil War. It appears to be not uncommon in the East.

Diagnosis.—The recognition of dysentery itself is rarely difficult. Some cases of ulcerative colitis may cause confusion, but local examination by the sigmoidoscope and the results of cultures should make the diagnosis clear.

Metallic poisoning, especially bichloride of mercury, may be mistaken for dysentery in the absence of a complete history, but chemical examination of the stools, the renal involvement and stomatitis should prevent error. Syphilis and carcinoma of the bowel should be excluded. The recognition of the *form* of dysentery is important, particularly for treatment. The amœbic, Bilharzial, and flagellate forms can generally be recognized by careful examination of fresh stools or the material obtained by a rectal tube or on direct examination. The dysentery bacillus may be obtained on culture from the stools. The agglutination test is usually positive. Houghwout emphasizes the value of a study of the cellular exudate as shown in the stools. In bacillary dysentery there is a rich purulent exudate, consisting mainly of polymorphonuclear leucocytes (about 90 per cent.) and phagocytic endothelial macrophages. The cells show marked degeneration. In amœbic dysentery the exudate is scanty and without the inflammatory character of the bacillary form.

Prognosis.—Flint showed that sporadic dysentery is, in its slighter grades at least, a self-limited disease, which runs its course in eight or nine days. In epidemics the death rate averages 10 to 40 per cent. The outlook is serious in young children and in debilitated persons.

Treatment.—PROPHYLACTIC.—The same precautions should be followed as in typhoid fever. Flexner and Gay have shown that animals can be protected from infection by a previous treatment with immune serum. Protective and curative serums have been prepared. Vaccines, in doses of three billion have been given by mouth daily for three days, at least an hour before food.

I. ACUTE DYSENTERY.—The patient should be absolutely at rest in bed. He should be kept warm and have a flannel abdominal binder applied. The diet should be very simple—whey, egg albumen, barley or rice water, and strained gruels. Milk and lactose may be added later. Enough water should be given to relieve thirst. If vomiting occurs, nothing should be given by mouth for some hours, and if the patient requires fluid this can be given subcutaneously. Hot applications to the abdomen are useful. If the patient is seen early in the attack, free purgation is advisable, for which sodium sulphate and Rochelle salts are best. Either may be given in doses of two drams (8 gm.) for two doses an hour apart and later half the amount every three hours until the bowels have moved freely. By this treatment the course is sometimes cut short. If the attack is well established, the use of purgatives must be determined by the conditions present. If solid fecal matter is being passed, a purgative is indicated, castor oil being the best (5 vi, 25 c. c.). Until the bowels have been thoroughly cleared, purgation is indicated.

Medicinal.—Bismuth in large doses often has a beneficial effect. Thirty to sixty grains (2 to 4 gm.) should be given every hour. For the relief of pain and to quiet the bowel, morphia is the most useful drug and is to be preferred to opium by mouth. It should be given hypodermically (gr. $\frac{1}{4}$ to $\frac{1}{3}$, 0.016 to 0.022 gm.), and repeated according to the needs. If tenesmus is not marked, opium can be given as the starch and laudanum enema, in which 30 minims (2 c. c.) of laudanum are given. In severe cases salt solution may be given intramuscularly or 5 per cent. dextrose solution intravenously (up to 300 c. c.).

Local Treatment.—During the acute stages this may be out of the question, but should be employed whenever possible. Normal saline or sodium

bicarbonate (1 per cent.) solution at the body temperature can be used as an irrigation. This should be given very gently and with the hips elevated. If there is rectal irritation, a cocaine or morphia suppository should be given beforehand. As the symptoms lessen, the quantity of fluid can be increased and other solutions used, such as boric acid (5 per cent.) or alum (1 to 200).

With convalescence the diet should be increased very gradually and only simple foods allowed. The patient should be kept quiet until all danger of a relapse is over. This is most important to prevent chronic dysentery.

Specific Therapy.—Good results have been reported from the use of polyvalent serums, which should be given in doses of 50 to 100 c. c.

II. CHRONIC DYSENTERY.—The patient should be at rest in bed and on simple diet, milk, boiled, peptonized or fermented, whey, beef juice, and eggs. In some cases milk may have to be given well diluted or in small amounts, but it usually agrees well. It is well to give an occasional purge (castor oil, 5 ss, 15 c. c.) to empty the bowels. Drugs by mouth are not of great value. Bismuth, if used, should be in large doses (5 i, 4 gm.) every three hours while the patient is awake. Opium should not be given as a routine measure, as there is great danger of forming a habit. If employed, it is best given in the starch and laudanum enema. The serum is of little value; vaccine therapy is more promising.

Local Treatment.—This is most rational and should be carried out thoroughly. If the rectum is irritable, a cocaine or morphine suppository should be given previously. The irrigation, at the body temperature, should be given very gently, the patient encouraged to retain it as long as possible, and the amount gradually increased up to two litres if possible. One irrigation a day is usually enough. Silver nitrate solution is probably the best (1 to 5,000 at first and increased to 1 to 500). Boric acid (5 per cent.), salicylic acid (2 per cent.), alum, or tannic acid (3 per cent.) may also be used. With any of these an occasional irrigation of saline solution is useful. With improvement the frequency of the irrigations should be reduced. To any ulcers in the bowel which can be reached silver nitrate solution (25 per cent.) should be applied. In obstinate cases an appendicostomy or cæcostomy may be done and the bowel irrigated through the opening.

XIV. UNDULANT FEVER

Definition.—A specific fever caused by organisms of the *Brucella melitensis-abortus* group characterized by undulatory fever, sweating, arthritis and an enlarged spleen. The organisms fall into two serological types which are closely related. The *melitensis* is caprine and the *abortus* bovine and porcine. Both may infect man.

Distribution.—The disease as first recognized was derived from goat's milk and prevailed extensively in the Mediterranean littoral. Wherever goats were infected and the milk was drunk the disease occurred. From its prevalence in Malta arose the designation Malta fever. Bruce in 1886 isolated the organism *Brucella melitensis*. The work of recent years has shown that the organism which causes abortion in cattle (Bang in 1897 described it as *Bacillus abortus*) has close relations with *Brucella melitensis* (Evans). They

are regarded as distinct serological types of the same species. Wherever infection of animals with *B. abortus* occurs, and that is wherever there are cattle, the disease, undulant fever, may be conveyed to man.

Etiology.—The detection of the cause of undulant fever in Malta as due to *B. melitensis* conveyed in infected goat's milk was a brilliant piece of work, due largely to Marston, Bruce and Hughes. The recognition of the close relationship between the organisms was due to A. E. Evans (1918). Later proof of the occurrence of infection due to *B. abortus* in man was found (Keefer, 1924; Carpenter *et al.*, 1926). The recognition of this infection has been rapid and cases have been reported from many countries. A considerable number of cases have been reported in North America and Great Britain. Infection is usually due to the use of raw dairy products as by drinking infected milk from goats or cows. There is evidence that the organisms may enter through the skin and those handling infected animals may so contract the disease. Infection has occurred in laboratory workers.

Symptoms.—In the *abortus* form as seen in the United States the onset is usually gradual with weakness followed by headache, anorexia, general aching, fever and sweating. Chilly sensations or chills occur in some cases. The features of the disease are very variable. The most common are headache, backache, frequent arthralgia, occasionally arthritis, one case showing intermittent hydrarthrosis (Baker, 1929), anorexia, constipation, urinary disturbances, orchitis, and profuse sweating. Nervous features are not uncommon, insomnia, restlessness, stupor, coma and neuritic pains. Loss of weight and strength is common. The appearance of the patient varies greatly; some hardly seem ill and ambulant cases are not rare. In some cases the patient keeps at work despite some fever. Bronchitis may occur. Abdominal tenderness may be found. The spleen and the liver may be increased in size.

Fever.—The temperature record may show many variations. The most common curve in the American cases seems to be one with a marked remittent or intermittent course. Records of 98°-100° F. in the morning to 101°-102° in the evening may be regarded as an average range. The extreme variation should be recognized. There does not seem to be the same tendency to relapsing forms in the American as in the Mediterranean cases. The termination is usually by lysis. The pulse shows no striking changes. The blood shows some secondary anæmia. There is usually a leucopenia with an increase in the total of the mononuclear cells.

The duration of the disease may be from a few weeks to a year or longer. There is a remarkable tendency to recurrences. The mortality is low and averages 2 or 3 per cent.

Diagnosis.—This disease has to be considered as a possibility in all doubtful cases of fever and the assistance of thorough laboratory work is important. Blood cultures should be made as early as possible. The agglutination test is of great value and should be done in all suspicious cases. Agglutination in a dilution of 1-80 should be demanded; in a dilution of 1-40, suspicion should be aroused and further studies made. A dermal reaction, using diluted vaccine, has been used. The frequency of ambulatory cases and the slight grade of fever in some instances, especially in those with digestive disturbance or weakness as the main symptom, suggest the wisdom of agglutination tests and a consideration of this disease in what may seem to be slight febrile ailments.

Prophylaxis.—In localities where goats' milk is drunk, its use should be abandoned or the milk thoroughly boiled. The *abortus* form is due to drinking raw milk or cream. Pasteurization should be done or the milk boiled. Particular care should be taken in the country in districts where abortion in cattle occurs. The organisms may be in large numbers in the vaginal discharges of infected animals and infect those working with them.

The difficulty of *prophylaxis* in country districts is evident. Milk should be boiled or pasteurized on farms where the cows are infected. Special care should be taken, especially by the dairymen, to avoid infection by the hands.

Treatment.—General measures suitable to typhoid fever are indicated. Fluid food should be given during the febrile period. Hydrotherapy, either the bath or the cold pack, should be used when the temperature is above 103° F. There are some favorable reports from the use of chemotherapy in the form of mercurochrome or acriflavine intravenously. Foreign protein therapy has been employed. Otherwise the treatment is symptomatic as no drugs by mouth appear to have any special influence. A change of climate seems to promote convalescence.

XV. CHOLERA ASIATICA

Definition.—A specific, infectious disease, caused by the "comma bacillus" of Koch, and characterized clinically by violent purging and rapid collapse.

Historical Summary.—Cholera has been endemic in India from a remote period, but only within the last century did it make inroads into Europe and America. An extensive epidemic occurred in 1832, in which year it was brought in immigrant ships from Great Britain to Quebec. It travelled along the lines of traffic up the Great Lakes, and finally reached as far west as the military posts of the upper Mississippi. In the same year it entered the United States by way of New York. There were recurrences of the disease in 1835-36. In 1848 it entered the country through New Orleans, and spread widely up the Mississippi Valley and across the continent to California. In 1849 it again appeared. In 1854 it was introduced by immigrant ships into New York and prevailed widely throughout the country. In 1866 and in 1867 there were less serious epidemics. In 1873 it again appeared in the United States, but did not prevail widely. Although occasional cases have been brought by ship to the quarantine stations of Great Britain and the United States, the disease has not gained a foothold in either country since 1873. It has prevailed extensively in the Philippines and in the Near and Far East. In 1911 cholera prevailed in Italy, North Africa and Madeira. There were outbreaks in Asia Minor, Arabia and Turkey, and the usual prevalence in India. To the United States, during 1911, cholera was frequently conveyed by ships from Italy, but there was no difficulty in controlling it. A number of cholera "carriers" were found.

Etiology.—In 1884 Koch announced the discovery of the specific organism. It has the form of a slightly bent rod, which is thicker, but not more than about half the length of the tubercle bacillus, and sometimes occurs in corkscrew-like or S forms. The organisms grow upon a great variety of media and display characteristic appearances. Koch found them in the water tanks

in India, and they were isolated from the Elbe water during the Hamburg epidemic of 1892. During epidemics virulent bacilli may be found in the faeces of healthy persons. The bacilli are found in the intestine, in the stools from the earliest period of the disease, and very abundantly in the rice-water evacuations, in which they are found in almost pure culture. They very rarely occur in the vomit. Post mortem, they are found in enormous numbers in the intestine. In acutely fatal cases they do not seem to invade the intestinal wall, but in those with a more protracted course they are found in the glands and in the deeper tissues. Varieties of paracholera organisms are described.

IMMUNITY.—Animals may be immunized by repeated injections of non-fatal doses of the dead and later of the living organisms. The serum of an immunized animal has agglutinative and other antibacterial properties. The blood serum of convalescent patients also possesses these properties.

Modes of Infection.—As in other diseases, individual peculiarities count for much, and during epidemics virulent cholera bacilli have been isolated from the normal stools of healthy men. Cholera cultures have also been swallowed with impunity.

The disease is not highly infectious; physicians, nurses, and others in close contact with patients are not often affected. On the other hand, washerwomen and those who handle the linen of the cholera patients, or their stools, are particularly prone to contract the disease. There have been several instances of so-called "laboratory cholera," in which students have been accidentally infected while working with the cultures and at least one death has resulted. Vegetables which have been washed in infected water may convey the disease. Milk may also be contaminated. The bacilli live on fresh bread, butter, and meat, for from six to eight days. The possibility of the infection of food by flies should be borne in mind, since the bacilli may live for at least three days in their intestines.

The disease is propagated chiefly by contaminated water and the virulence of an epidemic in any region is in direct proportion to the imperfection of its water-supply. In India the demonstration of the connection between drinking-water and cholera infection is complete. The Hamburg epidemic is a most remarkable illustration. The unfiltered water of the Elbe was the chief supply, although taken from the river in such a situation that it was directly contaminated by sewage. In August, 1892, there was a sudden explosive epidemic, and within three months nearly 18,000 persons were attacked, with a mortality of 42.3 per cent. The neighboring city of Altona, which also took its water from the Elbe, but which had an efficient filtration system, had in the same period only 516 cases.

Two main types of epidemics are recognized: the first, in which many individuals are attacked simultaneously, as in the Hamburg outbreak, and in which there is widespread contamination of the drinking-water. In the other the cases occur in groups, so-called cholera nests; individuals are not attacked simultaneously, but successively. A direct connection between the cases may be very difficult to trace. Both these types may be combined, and in an epidemic which has started in a widespread infection through water, there may be other outbreaks, examples of the second type. The disease always follows the lines of human travel. In India it has, in many notable

cases, been spread by pilgrims. It is carried also by caravans and in ships.

Cholera *carriers* have an important influence. In Manila nearly 8 per cent. of 376 healthy persons harbored the bacilli. Perennial outbreaks in the Manila prison were due to carriers, 17 of whom were found among those who had to do with the preparation of the food and drink of 3,000 prisoners.

The disease affects persons of all ages. It is particularly prone to attack the intemperate and those debilitated by want of food and by bad surroundings. Depressing emotions, such as fear, may have an influence. It is doubtful whether an attack furnishes immunity against a second one.

Morbid Anatomy.—A post-mortem diagnosis can be made by any competent bacteriologist, as the organism is distinctive. The body has the appearances associated with profound collapse. There is often marked post mortem elevation of temperature. The *rigor mortis* sets in early and may produce displacement of the limbs. The lower jaw has been seen to move, the eyes to rotate and movements of the arms and legs have been noted. The blood is thick and dark, and there is a remarkable diminution in the amount of its water and salts. The peritoneum is sticky, and the coils of intestines are congested and look thin and shrunken. The small intestine usually contains a turbid serum, similar to that passed in the stools. The mucosa is, as a rule, swollen, and in very acute cases slightly hyperæmic; later the congestion, which is not uniform, is more marked, especially about the Peyer's patches. The bacilli are found in the contents of the intestine and in the mucous membrane. The spleen is usually small. The liver and kidneys show cloudy swelling, and the latter extensive coagulation-necrosis and destruction of the epithelial cells.

Symptoms.—A period of incubation of uncertain length, probably not more than from two to five days, precedes the onset of the symptoms.

Three stages may be recognized in the attack: the preliminary diarrhœa, the collapse stage, and the period of reaction.

(a) THE PRELIMINARY DIARRHŒA may set in abruptly without any previous indications. More commonly there are, for one or two days, colicky pains in the abdomen, with looseness of the bowels, perhaps vomiting, with headache and depression of spirits. There may be no fever.

(b) COLLAPSE STAGE.—The diarrhœa increases, or without any of the preliminary symptoms, sets in with the greatest intensity, and profuse liquid evacuations succeed each other rapidly. There are in some instances griping pains and tenesmus. More commonly there are exhaustion and collapse. The thirst becomes extreme, the tongue is white; cramps of great severity occur in the legs and feet. Within a few hours vomiting sets in and becomes incessant. The patient rapidly sinks into a condition of collapse, the features are shrunken, the skin has an ashy-gray hue, the eyeballs sink in the sockets, the nose is pinched, the cheeks are hollow, the voice becomes husky, the extremities are cyanosed, and the skin is shriveled, wrinkled, and covered with perspiration. The temperature sinks and in the axilla or the mouth may be from five to ten degrees below normal, but in the rectum it may be 103° or 104°. The blood pressure falls greatly and is often below 70 mm. Hg. The pulse becomes extremely feeble and the patient passes into a condition of coma, though consciousness is often retained until near the end. Uræmia with acidosis is common.

The stools are at first yellowish in color but soon become grayish-white and look like turbid whey or rice-water; whence the term "rice-water stools." Numerous small flakes of mucus and granular matter, and at times blood are found in them. The reaction is usually alkaline. The fluid contains albumin and the chief mineral ingredient is chloride of sodium. Microscopically, mucus and epithelial cells and innumerable bacteria are seen.

The condition of the patient is largely the result of the concentration of the blood consequent upon the loss of serum in the stools. Acidosis has some influence. The specific gravity of the blood rises to 1.060 to 1.072. There is almost complete arrest of secretion of saliva and urine, but the sweat-glands increase in activity, and in nursing women it has been stated that the lacteal flow is unaffected. This stage sometimes lasts not more than two or three hours, but more commonly from twelve to twenty-four.

(c) REACTION STAGE.—When the patient survives the collapse, the cyanosis gradually disappears and warmth returns to the skin, which may have for a time a mottled color or present a definite erythematous rash. The heart's action becomes stronger, the urine increases in quantity, the irritability of the stomach disappears, the stools are at longer intervals, and there is no abdominal pain. In the reaction the temperature may not rise above normal. Not infrequently this is interrupted by a recurrence of severe diarrhœa and the patient is carried off in a relapse. Other cases pass into the condition of what has been called *cholera-typhoid*, in which the patient is delirious, the pulse rapid and feeble, and the tongue dry. Death finally occurs with coma. These symptoms have been attributed to uræmia and acidosis.

During epidemics attacks are found of all grades of severity. There are cases of diarrhœa with griping pains, liquid stools, vomiting, and cramps, with slight collapse. They resemble the cases of *cholera nostras*. At the opposite end of the series are the instances of *cholera sicca*, in which death may occur in a few hours after the onset, without diarrhœa.

Complications and Sequelæ.—The consecutive nephritis rarely induces dropsy. Diphtheritic colitis has been described. There is a special tendency to diphtheritic inflammation of the mucous membranes, particularly of the throat and genitals. Pneumonia and pleurisy may follow, and destructive abscesses may occur in different parts. Suppurative parotitis is not very uncommon. In rare instances local gangrene may occur. A troublesome symptom of convalescence is cramps in the muscles of the arms and legs.

Diagnosis.—Difficulty may occur from *cholera nostras*, the severe choleraic diarrhœa which occurs during the summer months in temperate climates. The clinical picture of the two affections is identical. The extreme collapse, vomiting, and rice-water stools, the cramps, the cyanosed appearance, are all seen in the worst forms of *cholera nostras*. In enfeebled persons death may occur within twelve hours. The diagnosis has to be made by bacteriological methods.

Attacks very similar to Asiatic cholera are produced in poisoning by arsenic, corrosive sublimate, and certain fungi; but a difficulty in diagnosis could scarcely arise.

The *prognosis* is always uncertain, as the mortality ranges in different epidemics from 30 to 80 per cent. Intemperance, debility, and old age are unfavorable conditions. The more rapidly the collapse sets in, the greater is

the danger, and as Andral truly says of the malignant form, "It begins where other diseases end—in death." Patients with marked cyanosis and very low temperature rarely recover.

Prophylaxis.—Preventive measures are all-important, and isolation of the sick and thorough disinfection have effectually prevented the disease entering England or the United States since 1873. During epidemics the greatest care should be exercised in the disinfection of the stools and linen of the patients. When an epidemic prevails, persons should not drink water unless previously boiled. The milk should be boiled and all food and drinks carefully protected from flies. Uncooked vegetables and salads should not be eaten. As the disease is not more infectious than typhoid fever, the chance of passing safely through an epidemic depends very much upon how far one is able to carry out prophylactic measures thoroughly. Digestive disturbances are to be treated promptly, particularly diarrhœa, which so often is a preliminary symptom. For this, opium and large doses of bismuth should be given. Protective inoculation by vaccines has been carried out with success. In epidemics it is important to search for cholera "carriers" and isolate them. The stools from patients should be thoroughly disinfected and protected from flies.

Treatment.—The patient should be at rest in bed, kept warm, and given boiled milk, whey and egg albumen. Water may be given freely. If vomiting occurs food should be withheld and the stomach washed with an alkaline solution. Hot applications to the abdomen should be used and hot baths given if they prove helpful. Early in the course the bowels should be moved by castor oil or calomel. It is best not to attempt to give remedies by the mouth, as they disturb the stomach, but kaolin (a suspension in water given *ad lib.*) appears to be useful if given early. In the collapse stage, writers speak strongly against the use of opium. Undoubtedly it must be given with caution, but, judging from its effects in cholera nostras, it would seem that collapse *per se* is not a contraindication. Potassium permanganate (gr. ii, 0.13 gm. in keratin coated pills) is given every 15 minutes for two to four hours and then every half hour until the color of the stools is green or yellow. For collapse pituitary extract and caffeine are useful.

Owing to the profuse serous discharges the blood becomes concentrated and to meet this, intravenous injections were introduced by Latta, of Leith, in the epidemic of 1832. Bovell first practised the intravenous injections of milk in Toronto, in the epidemic of 1854. Saline injections, intravenous and into the bowel, have been much used and with great success by the method introduced by Leonard Rogers. The hypertonic solution is composed of sodium chloride, grains 120; potassium chloride, grains 6; calcium chloride, grains 4; water, 1 pint. If the blood pressure is below 70 or the specific gravity of the blood 1.063 or over the hypertonic solution is given intravenously (1500-3000 c. c.) and repeated as often as required to keep the blood pressure above 70 and the specific gravity below 1.063. Normal saline solution (500 c. c.) with glucose (5 per cent.) is given by the bowel every two hours and at longer intervals if the urine increases. If there is suppression of urine with the danger of uræmia, sodium chloride 4 gm. and sodium bicarbonate 10 gm. in 500 c. c. of water are given intravenously. This treatment has markedly reduced the mortality.

In the stage of reaction special pains should be taken to regulate the diet

and to guard against recurrences of the severe diarrhœa. If this occurs potassium permanganate and kaolin may be given by mouth and the use of astringent solutions by injection into the bowel may be tried. The amount of urinary secretion should be watched carefully and if it becomes small in amount, alkaline solutions should be given intravenously or subcutaneously. In convalescence the diet should be simple and a long period of rest advised.

XVI. THE PLAGUE

Definition.—A specific, infectious disease, caused by *Bacillus pestis*, and occurring in two chief forms: a bubonic, involving the lymphatic glands, and a pneumonic, causing an acute and rapidly fatal inflammation of the lungs.

History and Geographical Distribution.—The disease was probably not known to the classical Greek writers. The earliest positive account dates from the second century of our era. The plague of Athens and the pestilence of the reign of Marcus Aurelius were apparently not this disease (Payne). From the great plague in the days of Justinian (sixth century) to the middle of the seventeenth century epidemics of varying severity occurred in Europe. Among the most disastrous was the famous “black death” of the fourteenth century, which overran Europe and destroyed a fourth of the population. In the seventeenth century it raged virulently, and during the great plague of London, in 1665, about 70,000 people died. During the eighteenth and nineteenth centuries the ravages of the disease lessened.

The revival of the plague is the most important single fact in modern epidemiology. Throughout the nineteenth century it waned progressively, outbreaks of some extent occurring in Turkey and Asia Minor and Astrakan; but we had begun to place it with sweating sickness among the diseases of the past. We knew that it slumbered in parts of China, and in northwest India, but the outbreak in 1894 at Hong-Kong showed that the “black death” was still virulent. Since then it has spread in an ominous manner over many parts of the world. In Europe, cases have been carried to Marseilles and other Mediterranean ports and to Hamburg and Glasglow. There have been small outbreaks in the United States at intervals from 1907 to the present with infection of rats and ground squirrels.

The distribution in India is chiefly in the Punjab, Bombay, and the United Provinces, which have a combined population of about 100 millions. In these three provinces between 1896 and the middle of 1911, about five and a half million deaths occurred from plague. In the remaining provinces of India, with a population of some 200 millions, only about two millions of plague deaths occurred. There have been outbreaks in China, and the disease has been reported in Egypt, Japan, Straits Settlements, Java and Sumatra, Persia, Turkey in Asia, Astrakan, the Mauritius, and several South American countries. The Manchurian outbreak of pneumonic plague in the winter of 1910-11 was one of the most virulent on record, carrying off more than 45,000 persons in a few months.

Etiology.—The specific organism is a bacillus discovered by Kitasato. It resembles somewhat the bacillus of chicken cholera, and grows in a characteristic manner. *B. pestis* occurs in the blood, in the organs of the body

and in the sputum, and has also been found in the dust and in the soil of houses in which the patients have lived, but outside the body the life of the bacillus is thought to be short. Bed-bugs may harbor it.

The disease prevails most frequently in hot seasons, though an outbreak may occur during the coldest weather. Persons of all ages are attacked. It spreads chiefly among the poor, in the slums of the great cities.

The following conclusions of the Plague Commission (1908) relate to bubonic plague: (a) Contagion occurs in less than 3 per cent. of the cases, playing a very small part in the general spread of the disease. (b) Bubonic plague in man is entirely dependent on the disease in the rat. (c) The infection is conveyed from rat to rat and from rat to man solely by means of fleas. (d) A case in man is not in itself infectious. (e) A large majority of cases occur singly in houses. When more than one case occurs in a house, the attacks are generally nearly simultaneous. (f) Plague is usually conveyed from place to place by imported fleas, which are carried by people on their persons or in their baggage. The human agent may himself escape infection. (g) Insanitary conditions have no relation to the occurrence of plague, except in so far as they favor infestation by rats. (h) The non-epidemic season is bridged over by acute plague in the rat, accompanied by a few cases among human beings.

In the pneumonic form direct infection from one person to another is the common way, as the bacilli are sprayed into the air by coughing. The possibility of the human flea as a carrier must be considered.

Clinical Forms.—PESTIS MINOR.—In this variety, also known as the ambulant, the patient has a few days of fever, with swelling of the glands of the groin, and possibly suppuration. He may not be ill enough to seek medical relief. These cases, often found at the beginning and end of an epidemic, are a very serious danger, as the urine and fæces contain bacilli.

BUBONIC PLAGUE.—This constitutes the common variety. The stage of invasion is characterized by headache, backache, stiffness of the limbs, a feeling of anxiety and restlessness, and great depression of spirits. There is a steady rise in the fever until the third or fourth day, when there is a drop of two or three degrees. There is then a secondary fever, in which the temperature reaches a still higher point. The tongue becomes brown, collapse symptoms are apt to supervene, and in very severe infections the patient may die at this stage. In at least two-thirds of all cases there are glandular swellings or buboes. An analysis of 9,500 cases of buboes gave more than 54 per cent. with the glands of the groin affected. The swelling appears usually from the third to the fifth day. Resolution may occur, or suppuration, or in rare cases gangrene. Suppuration is a favorable feature, as noted by De Foe in his graphic account of the London plague. There is a high leucocytosis.

Petechiæ very commonly show themselves, and may be very extensive. These have been called the "plague spots," or the "tokens of the disease," and gave to it in the middle ages the name of the Black Death. Hæmorrhages from the mucous membranes may also occur; in some epidemics hæmoptysis has been especially frequent.

SEPTICÆMIC PLAGUE.—In this, the most rapid form, the patient succumbs in three or four days with a virulent infection before the buboes appear. Hæmorrhages are common. The bacilli can be obtained from the blood.

PNEUMONIC PLAGUE.—In the ordinary bubonic type, inflammation of the lungs is not an uncommon complication, but the true pneumonic plague begins abruptly with fever, shortness of breath, cough, and sometimes pain in the chest. The fever increases, the signs of the involvement of the lung occur early; there may be impaired resonance at both bases with harsh and tubular breathing; the sputum becomes bloody and is more fluid than in ordinary pneumonia. Cyanosis is an early feature; the pulse is small and rapid; the spleen enlarges rapidly, as early as the second day, and a fatal result follows in from two to four days. Recovery is very rare.

In other varieties the chief manifestations may be in the skin and subcutaneous tissues, or in the intestines, causing diarrhoea and sometimes the features of typhoid fever.

Diagnosis.—At the early stage of an outbreak plague cases are easily overlooked, but if the suspicious cases are studied by a competent bacteriologist, there is no disease which can be more positively identified. The San Francisco epidemic illustrates this. The nature of the cases was recognized by Kellog and by Kinyoun, but with an amazing stupidity (which was shared by not a few physicians, who should have known better) the Governor of the State refused to recognize the presence of plague, and the United States Government had to intervene and send a board of experts to settle the question. The finding of marked lymph node swelling may suggest the diagnosis, but a definite conclusion must depend on the bacteriological study. Acute, rapidly fatal pneumonia or septicæmia should arouse suspicion.

Prophylaxis.—Wherever plague exists an organized staff, an intelligent policy, and a long purse are needed. In India, where fifteenth-century conditions prevail, and where the scale of the epidemic is so enormous, the problem of prophylaxis looks hopeless. A careful watch should be kept on the mortality of rats. When found infected, energetic measures should be taken to destroy them. Three things are necessary—the cleansing of premises, particularly stables and outhouses, so that the rats cannot find nesting places or food; systematic rat destruction; and making houses rat proof. Certain measures prevent the access of plague to healthy ports; fumigation of ships to destroy the rats, careful inspection of passengers and crew, and detention over a period which covers the incubation of the disease.

When a centre becomes infected, the sanitary organization should carry out the segregation of the sick in hospitals, the disinfection of infected rooms, destruction of infected bedding, and thorough cleansing of the entire district; old, badly infected buildings should be destroyed.

Preventive Inoculation.—With Haffkine's vaccine in 12 districts of 224,228 persons inoculated, 3,399 took the disease; of 639,600 uninoculated, 49,430 were attacked. C. J. Martin concludes that the chances of infection are reduced four-fifths, and the chances of recovery are two and a half times as great as in the uninoculated. The reports from India are most favorable and in South America the value of this plan has been demonstrated. It is interesting to note that the laboratory staff at Bombay, 116 in number, have remained immune though in constant contact with plague infested rats.

Treatment.—In a disease the mortality of which may reach as high as 80 or 90 per cent. the question of treatment resolves itself into making the patient

as comfortable as possible, and following out certain general principles such as guide us in the care of fever patients. Cantlie recommends purgation and stimulation from the outset, and the use of morphia for the pain. The local treatment of the buboes is important. Ice may be applied to them, and good results apparently follow the injection of bichloride of mercury. The pyrexia of the disease is best treated by systematic hydrotherapy.

A plague serum, chiefly the Lustig and the Yersin-Roux, has been used. Doses of 100-200 c. c. are necessary. Choksy concludes that a reduction of 20-25 per cent. in the mortality may be obtained by its use.

XVII. TETANUS (LOCKJAW)

Definition.—An infectious malady characterized by tonic spasms of the muscles with marked exacerbations. The *Bacillus tetani* of Nicolaier occurs in earth, in putrefying fluids, and manure, and is a normal inhabitant of the intestines of many animals.

Etiology.—In the United States, according to Anders and Morgan, it is most frequent in the Hudson valley, in Long Island and in the Atlantic States. In 1920 there were 1,349 deaths from tetanus in the U. S. registration area, of which 309 were in children under one year. An extraordinary number of cases followed the accidents of the July 4th celebrations, but the propaganda of the Journal of the American Medical Association succeeded in reducing these fatalities in a remarkable way. In England the disease is not very common. There were 174 deaths in 1923. It is more prevalent in certain districts, e. g., the Thames valley. It is more common in the summer months and males are more frequently attacked than females. In E. W. Hill's analysis of 3,038 cases in temperate climates 22.31 per cent. were in children under one year, 21 per cent. in the third and fourth decades.

In the tropics tetanus is a much more severe and common disease. In Jamaica and Cuba it is from five to six times more frequent as a cause of death than in the United States, and above 80 per cent. of the deaths are in infants. It is not only in the tropics that tetanus is a very fatal disease in infants. For years the island of St. Kilda, one of the Western Hebrides, was scourged by the "eight days sickness" among the new born. Of 125 children, 84 died within fourteen days of birth. Since the introduction of proper methods of treating the umbilical cord the disease has practically disappeared.

The tetanus bacillus has contaminated vaccines, and its presence in commercial gelatine is a danger. Outbreaks have occurred in hospitals from infected catgut. The disease has occurred after prolonged use of the hypodermic needle and has followed the use of gelatine as a hæmostatic.

The disease usually follows an injury, often of a most trifling character, and particularly lacerated wounds of the hands which have been contaminated by dirt and splinters. It may occur without any recognizable wound, so-called idiopathic tetanus.

THE TETANUS BACILLUS.—The organism is widely diffused in earth, in garden mould, in and about stables and farmyards, and is a normal inhabitant of the intestines of many herbivora. Living bacilli occur in the intestines

of 5 per cent. of healthy men and up to 20 per cent. of hostlers and dairymen. It is a slender motile bacillus, one end of which is swollen and occupied by a spore. It is anaërobic and grows at ordinary temperatures. The spores are the most resistant known. From two steel nibs dipped in a tetanus culture in 1891 a growth of virulent bacilli was obtained from one in 1902 and from the other in 1909 (Semple). The spores may remain in the tissues for months. The toxin is perhaps the most virulent of known poisons. Whereas the fatal dose of strychnine for a man weighing 70 kilos is from 30 to 100 milligrammes, that of the tetanus toxin is estimated at 0.23 milligramme. Every feature of the disease can be produced by it experimentally without the presence of the bacilli. The symptoms do not arise immediately, but slowly, and it has been found to be absorbed by the end plates in the muscles and to pass up the motor nerves to the spinal cord. The period of incubation is the time required for the toxins to travel along the nerves to the centres. The toxin enters the blood and is excreted in the urine of patients. A high degree of anti-toxic immunity can be conferred on animals, which then yield a protective serum. It is stated that the blood serum of persons with the bacilli in the intestines contains more antitoxin.

Morbid Anatomy.—No characteristic lesions have been found in the cord or in the brain. Congestions occur in different parts, and perivascular exudations and granular changes in the nerve-cells have been found. The condition of the wound is variable. The nerves are often found injured, reddened, and swollen. In tetanus neonatorum the umbilicus may be inflamed.

Symptoms.—The incubation period is from one to twenty days. Of 1,092 cases analyzed by E. W. Hill, in 17.49 per cent. it was from one to five days and in 55.06 per cent. from five to ten days. In only 8 cases was the incubation as long as twenty days. The patient complains at first of slight stiffness in the neck, or a feeling of tightness in the jaws, or difficulty in mastication. Occasionally chilly feelings or actual rigors may precede these symptoms. Sometimes the muscles near the wound show spasticity and increased excitability early. Gradually a tonic spasm of the muscles of these parts produces the condition of trismus or lockjaw. The eyebrows may be raised and the angles of the mouth drawn out, causing the so-called sardonic grin—*risus sardonicus*. In children the spasm may be confined to these parts. Sometimes the attack is associated with paralysis of the facial muscles and difficulty in swallowing, which has most commonly followed injuries in the neighborhood of the fifth nerve. Gradually the process extends and involves the muscles of the body. Those of the back are most affected, so that during the spasm the victim may rest upon the head and heels—*opisthotonos*. The rectus abdominis muscle has been torn across in the spasm. The entire trunk and limbs may be perfectly rigid—*orthotonos*. Flexion to one side is less common—*pleurothotonos*; while spasm of the muscles of the abdomen may cause the body to be bent forward—*emprosthotonos*. In very violent attacks the thorax is compressed, the respirations are rapid, and spasm of the glottis may occur, causing asphyxia. The paroxysms are momentary or last for several seconds but even in the intervals the relaxation is not complete. The slightest irritation is sufficient to cause a spasm. The paroxysms are associated with agonizing pain, and the patient may be held as in a vise, unable to utter a word. Usually

he is bathed in a profuse sweat. The temperature may remain normal, or show only a slight elevation toward the close. In other cases the pyrexia is marked from the outset; the temperature reaches 105° or 106° , and before death 109° or 110° . The leucocytes are increased. The spinal fluid usually shows increased pressure with a normal cell count and negative globulin test. The course is sometimes very rapid, with fever and general spasms; death may take place on the third day. Death occurs during the paroxysm from heart failure or asphyxia, or is due to exhaustion.

In those who have been given antitoxin as a preventive there may be anomalous forms. The onset of symptoms may be delayed for weeks or months and may be determined by a secondary operation. *Local tetanus* may be limited to muscles near the wound or to an extremity. In *chronic tetanus* the symptoms appear late, are not severe and may persist for a long time. Cephalic tetanus originates usually from a wound of the head, and is characterized by stiffness of the muscles of the jaw and paralysis of the facial muscles on the same side as the wound, with difficulty in swallowing. There may be no other symptoms. This form has been called hydrophobic because of the spasm of the throat. The prognosis is good in the chronic cases, which may show slight symptoms only.

Tetanus neonatorum occurs particularly in hot climates and in districts where the tetanus bacillus is very prevalent. The infection follows imperfect treatment of the navel. The symptoms may come on in a few days or be delayed for ten days. Trismus and difficulty in crying and taking food are the earliest symptoms, followed in a few days by more general spasms. It is very fatal. A form known as *visceral tetanus* is described by the French in which the disease originates in the intestines, and the possibility of this must be considered, as the organism may be present in the human intestine. *Post-operative tetanus* occurs particularly after peritoneal operations. Paterson collected 150 cases in a large proportion of which catgut had been used. It is very fatal with a short incubation and rapid course. Operation on an individual who has recovered from tetanus a short time before, may cause a relapse.

Diagnosis.—Well-marked cases following a trauma could not be mistaken for any other disease. The spasms are not unlike those of *strychnia poisoning*, and in the celebrated Palmer murder trial this was the plea for the defence. The jaw-muscles, however, are never involved early, if at all, and between the paroxysms in strychnia poisoning there is no rigidity. In *tetany* the distribution of the spasm at the extremities, the peculiar position, the greater involvement of the hands, and the condition under which it occurs make the diagnosis clear. In doubtful cases cultures should be made from the pus of the wound. In *hydrophobia* there is the history of a bite, there is no continuous rigidity and the spasms are particularly of the muscles of respiration and deglutition. In meningitis and hysteria a careful examination should prevent error. A mild trismus may occur with throat and mouth infection and should not be mistaken for head tetanus.

Escherich described in children a form of generalized tonic contractures of the muscles of the jaw, neck, back, and limbs, usually a sequel of some acute infection, occasionally occurring as an independent malady. The contractures

may be intermittent or persistent. The condition may last from a week to a couple of months. The patients as a rule recover.

Prognosis.—Two of the Hippocratic aphorisms express tersely the general prognosis: "The spasm supervening on a wound is fatal," and "such persons as are seized with tetanus die within four days, or if they pass these they recover." Of 1,264 cases (E. W. Hill) only 414 recovered. If the disease lasts beyond the tenth day the patient has an even chance, and from this time the prognosis improves. The mortality is greatest in children. Favorable indications are: late onset of the attack, localization to the muscles of the neck and jaw, an absence of fever, anomalous forms and a prompt administration of antitoxin after the injury.

Prophylaxis.—Suspicious wounds should be freely opened and thoroughly disinfected by hydrogen peroxide and iodine. In districts where the disease prevails, special precautions should be taken with all injuries, and a prophylactic dose of anti-tetanic serum (500 to 1,500 units) administered. The experience in the United States with this treatment in the Fourth of July accidents has been most satisfactory. It should be carried out promptly in all street and infected injuries. As the serum is expensive, Boards of Health should arrange, if necessary, to provide it. The experience of the Great War showed the value of antitoxin as a preventive. In the U. S. Civil War the incidence was one case of tetanus among 487 wounded; in the U. S. troops in the Great War it was one among 6,224 wounded.

Treatment.—The patient should be kept in a darkened room, absolutely quiet, and attended by only one person. All possible sources of irritation should be avoided. Veterinarians appreciate the importance of this complete seclusion in treating horses.

When the lockjaw is extreme the patient may not be able to take food by the mouth and it is best to use rectal injections or feed by a catheter passed through the nose. The spasms should be controlled by chloroform, which may be repeatedly used. It is well to keep the patient thoroughly under the influence of morphia given hypodermically. Chloral hydrate, chlorotone, and bromide of potassium may be helpful. Pheno-barbital (luminal) may be effectual, 3-5 grains (0.2-0.3 gm.) being given by mouth or rectum every few hours. Intraspinal injections of a solution of magnesium sulphate (25 per cent.) have been used (Meltzer); 1 c. c. is injected for every 25 pounds weight of the patient. *Tetanus antitoxin* should be given promptly and in sufficient dosage, the object being to saturate the patient as quickly as possible. The wound should be cleaned, if necessary, and left open with a dry sterile dressing; 5,000 units of antitoxin should be injected about the wound. The antitoxin should be given intravenously (20,000 units) with the usual precaution of 1 c. c. subcutaneously to desensitize; thirty minutes later the serum is given slowly, diluted with an equal volume of salt solution. Lumbar puncture is done—for which an anæsthetic is generally advisable—and if possible 10,000 units are given intraspinally. The same dosage, intravenously and intraspinally, is given on the two following days. Intramuscular injections of 5,000 units are given daily from the fifth to the eighth day of treatment. These doses are large and improvement may suggest a decrease in the dosage on the second or third day but it must be remembered that the failure of anti-

toxin in *treatment* has often been due to insufficient dosage. Smaller doses can be given to young children. Sometimes after a period of improvement severe symptoms recur. In this event the serum should be given again intravenously and intraspinally.

XVIII. GLANDERS

(*Farcy*)

Definition.—An infectious disease of the horse and ass, caused by *Bacillus mallei*, communicated occasionally to man, characterized by the formation of nodules, chiefly in the nares (glanders) and beneath the skin (farcy).

Etiology.—The disease belongs to the infective granulomata. The specific germ is a short, non-motile bacillus, not unlike that of tubercle, but it exhibits different staining reactions. It grows readily on the ordinary culture media. For the full recognition of glanders in man we are indebted to Rayer, whose monograph remains one of the best descriptions of the disease. Man becomes infected by contact with diseased animals, and usually by inoculation on an abraded surface. In a Montreal case a man was probably infected by the material expelled from the nostril of his horse, which was not suspected of having the disease. It is a rare disease. Only 12 deaths were registered from this cause in England and Wales from 1912 to 1928 inclusive, and 59 deaths in the U. S. registration area from 1911 to 1920. Among laboratory workers the *Bacillus mallei* has caused a number of deaths and in working with it the greatest precautions should be taken.

Morbid Anatomy.—As in the horse, the disease may be localized in the nose (glanders) or beneath the skin (farcy). The essential lesion is the granulomatous tumor, characterized by the presence of numerous lymphoid and epithelioid cells, among and in which are seen the glanders bacilli. These nodular masses tend to break down rapidly, and on the mucous membrane result in ulcers, while beneath the skin they form abscesses. The glanders nodules may also occur in the internal organs.

Symptoms.—An acute and a chronic form of glanders may be recognized in man, and an acute and a chronic form of farcy.

ACUTE GLANDERS.—The period of incubation is rarely more than three or four days. There are signs of general febrile disturbance. At the site of infection there are swelling, redness, and lymphangitis. Within two or three days there is involvement of the mucous membrane of the nose, the nodules break down rapidly to ulcers, and there is a muco-purulent discharge. An eruption of bullæ or papules, which rapidly become pustules, breaks out over the face and about the joints. It has been mistaken for variola. There may be areas in the subcutaneous tissue which break down; gangrene may follow. There is a great swelling of the nose. There may be an eruption like erysipelas. The ulceration may go on to necrosis, in which case the discharge is very offensive. The lymph-glands of the neck are usually much enlarged. This form runs its course in about eight or ten days, and is invariably fatal. *Glanders pneumonia* may appear after subcutaneous infection (one case from infection

with a hypodermic syringe stuck into the thumb). Grossly the lung appeared like a caseous pneumonia.

CHRONIC GLANDERS is rare and is usually mistaken for a chronic coryza. There are ulcers in the nose and often laryngeal symptoms. It may last for months, or even longer, and recovery sometimes takes place. Tedeschi described a case of chronic osteomyelitis, due to the *B. mallei*, which was followed by a fatal glanders meningitis. The diagnosis may be extremely difficult. In such cases a suspension of the secretion, or of cultures upon agar-agar made from the secretion, should be injected into the peritoneal cavity of a male guinea-pig. At the end of two days, in positive cases, the testicles are found to be swollen and the skin of the scrotum reddened. The testicles continue to increase in size, and finally suppurate. Death takes place after two or three weeks, and generalized glanders nodules are found in the viscera. The use of *mallein* for diagnostic purposes is highly recommended.

ACUTE FARCY in man results usually from an inoculation into the skin. There is an intense local reaction with a phlegmonous inflammation. The lymphatics are early affected, and along their course there are nodular subcutaneous enlargements, the so-called farcy buds, which may rapidly go on to suppuration. There are pains and swelling in the joints, and abscesses may form in the muscles. The symptoms are those of an acute infection, almost like an acute septicæmia. The nose is not involved and the superficial skin eruption is not common. The bacilli have been found in the urine in acute cases in man and animals. The disease is fatal in a large proportion of the cases, usually in from twelve to fifteen days.

CHRONIC FARCY is characterized by the presence of localized tumors which break down into abscesses, and sometimes form deep ulcers, without much inflammatory reaction and without special involvement of the lymphatics. The disease may last for months or years. Death results from pyæmia or acute glanders develops. The French veterinarian Bouley had it and recovered.

In **diagnosis** the occupation is very important. The acute forms may be mistaken for small-pox or septico-pyæmia and the chronic forms for syphilis or tuberculosis. In cases of doubt the inoculation should be made in animals or the complement fixation test used. In the acute cases there is very little hope. In the chronic cases recovery is possible, though often tedious.

Treatment.—If seen early, the site of inoculation should be excised or destroyed by caustics and an antiseptic dressing applied. The farcy buds should be opened early. Antiseptic solutions such as potassium permanganate and hydrogen peroxide should be used. Vaccine treatment may be tried cautiously with doses from 10 to 100 millions every two to four days in chronic cases. Increase in dosage must be governed by the reaction. Those handling the patient should take great care to avoid infection.

Melioidosis, a disease of the Far East, is caused by *Bacillus whitmori*, closely related to *B. mallei*. It occurs in rodents and man is infected from them. The lesion is a caseous nodule which breaks down or coalesces into large caseous masses, especially in the lungs. In acute cases there are vomiting, diarrhœa and collapse with death in a few days. In less acute forms there are fever, multiple abscesses and caseation, and toxæmia. Recovery is rare. The *diagnosis* depends on finding the organism in the blood, urine, sputum or abscesses. The *treatment* is symptomatic.

XIX. ANTHRAX

(*Splenic Fever; Charbon; Wool-sorter's Disease*)

Definition.—An acute infectious disease caused by *Bacillus anthracis*, occurring in three forms, cutaneous, pulmonary and intestinal. In animals, particularly sheep and cattle, the disease has the character of an acute septicæmia with enlargement of the spleen—hence the name *splenic fever*. In man it occurs sporadically or as a result of accidental inoculation.

Etiology.—*Bacillus anthracis* is a non-motile, rod-shaped organism with a length of from 2 to 25 μ ; the rods are often united. The bacilli themselves are readily destroyed, but the spores are very resistant, and survive after prolonged immersion in a 5 per cent. solution of phenol, or withstand for some minutes a temperature of 212°. They are capable also of resisting gastric digestion. Outside the body the spores are in all probability very durable.

IN ANIMALS.—Geographically and zoologically the disease is widespread and is much more prevalent in Europe and Asia than in America. Its ravages among the herds of cattle in Russia and Siberia, and among sheep in parts of Europe, are not equalled by any other animal plague. In the United States anthrax is not very prevalent. In France from 6 to 10 per cent. of the sheep and about 5 per cent. of the cattle formerly died of it.

The disease is conveyed sometimes by direct inoculation, as by the bites and stings of insects, by feeding on carcasses of animals which have died of the disease, but more commonly by grazing in pastures contaminated by the germs. Pasteur thought that the earthworm played an important part in bringing to the surface the bacilli from the buried carcass of an infected animal. Certain fields may thus be infected for an indefinite period. It seems probable that, if the carcass is not opened or the blood spilt, spores are not formed in the buried animal and the bacilli quickly die.

IN MAN the disease results from infection through the skin, intestines or lungs. Workers in wool and hair, and persons whose occupations bring them into contact with animals or animal products, as stablemen, shepherds, tanners, and butchers, are specially liable to the disease. In the United States the disease is usually found in the workers in hides, in butchers, and in veterinarians. Cases have resulted from the use of infected shaving brushes. It is rare in general hospital work. In the United States there was an average of 33 deaths a year from 1911 to 1920 in the registration area and in England and Wales in 1923 there were 13 deaths. Ponder states that 40 per cent. of all the cases of anthrax in British leather workers are due to handling Chinese or East Indian goods; 80 per cent. of the cases are due to skin infection while handling hides at the docks or in the tanneries.

Various forms of the disease have been described, and two chief groups may be recognized: the external anthrax and the internal anthrax, of which there are pulmonary and intestinal forms.

Symptoms.—(a) **EXTERNAL ANTHRAX.**—At the site of inoculation, usually on an unprotected exposed surface—the hands, arms, neck, or face—there are, within a few hours, itching and uneasiness, and the gradual forma-

tion of a small papule, which soon becomes vesicular. Inflammatory induration extends around this, and within thirty-six hours at the site of inoculation there is a dark brownish eschar, at a little distance from which there may be a series of small silvery vesicles. The brawny induration may be extreme. The œdema produces very great swelling of the parts. The inflammation extends along the lymphatics, and the neighboring lymph-glands are swollen and sore. The fever at first rises rapidly, and the concomitant phenomena are marked. Subsequently the temperature falls, and in many cases becomes subnormal. Death may take place in from three to five days. In cases which recover the constitutional symptoms are slighter, the eschar gradually sloughs out, and the wound heals. The cases vary much in severity. In the mildest form there may be only slight swelling. At the site of inoculation a papule is formed, which rapidly becomes vesicular and dries into a scab, which separates in the course of a few days.

A form in which œdema is marked occurs in the eyelid, and also in the head, hand, and arm, and is characterized by the absence of the papule and vesicle forms, and by the most extensive œdema, which is associated with the presence of anthracomucin. The œdema reaches such a grade of intensity that gangrene results, and may involve a considerable area. The constitutional symptoms are extremely grave and the cases usually prove fatal.

The greatest fatality is seen with inoculation about the head and face, when the mortality, according to Nasarow, is 26 per cent.; the least in infection of the lower extremities, when it is 5 per cent.

In a case at the Johns Hopkins Hospital in 1895, in a hair-picker, there were most extensive enteritis, peritonitis, and endocarditis, which last lesion has been described by Eppinger. Meningitis has also occurred.

A feature in both these forms is the absence of feelings of distress or anxiety on the part of the patient, whose mental condition may be perfectly clear. He may be without any apprehension, even though the condition be most critical. In some cases there is no fever.

The *diagnosis* in most instances is readily made from the character of the lesion and the occupation of the patient. There is a remarkable freedom from pain which distinguishes anthrax from furuncle, carbuncle and cellulitis. When in doubt, the examination of the fluid from the pustule may show the presence of the anthrax bacilli. Cultures should be made, or a mouse or guinea-pig inoculated from the local lesion. The blood may not show the bacilli in numbers until shortly before death.

(b) INTERNAL ANTHRAX.—(1) *Intestinal Form*.—In these cases the infection results from eating the flesh or drinking the milk of diseased animals; it may, however, follow an external infection if the germs are carried to the mouth. This is a form which may affect many individuals together. Butler and Huber described an epidemic in which twenty-five persons were attacked after eating the flesh of an animal which had had anthrax. Six died in from forty-eight hours to seven days. The symptoms are those of intense poisoning. The disease may set in with a chill, followed by vomiting, diarrhœa, moderate fever, and pains in the legs and back. It may be mistaken for intestinal obstruction. In acute cases there are dyspnœa, cyanosis, great anxiety and restlessness, and toward the end convulsions or spasms of the muscles. Hæmorrhage may occur from the mucous membranes. Occasionally there are small

phlegmonous areas or petechiæ on the skin. The spleen is enlarged. The blood is dark and remains fluid for a long time after death. Late in the course the bacilli may be found in the blood.

(2) *Wool-sorter's Disease, Pulmonary Anthrax*.—This form occurs in establishments in which wool or hair is sorted and cleansed. The hair and wool imported from Russia and South America appear to have induced the largest number of cases. Many of these show no external lesion. The infective material has been swallowed or inhaled with the dust. There are rarely premonitory symptoms. The patient is seized with a chill, becomes faint and prostrated, has pains in the back and legs, and the temperature rises to 102° or 103°. The breathing is rapid, and he complains of much pain in the chest. There may be a cough and signs of bronchitis. The pulse is feeble and very rapid. There may be vomiting, and death may occur within twenty-four hours with symptoms of profound collapse. Other cases are more protracted, and there may be diarrhœa, delirium, and unconsciousness. The cerebral symptoms may be intense; in at least four cases the brain seems to have been chiefly affected and its capillaries stuffed with bacilli (Merkel). The recognition of wool-sorter's disease as a form of anthrax is due to J. H. Bell, of Bradford.

In certain instances the symptoms of internal anthrax are associated with the external lesions of malignant pustule. Meningitis may occur with anthrax bacilli in the spinal fluid.

The *rag-picker's disease* has been made the subject of an exhaustive study by Eppinger (*Die Haderkrankheit*, Jena, 1894), who has shown that it is a local anthrax of the lungs and pleura, with general infection.

Prognosis.—The disease is always serious and recovery is rare in the internal forms. Cutaneous lesions about the face are more serious than on the extremities; the mortality has been high in the cases due to infected shaving brushes. Marked toxæmia and the occurrence of bacilli in the blood are of grave omen. Meddlesome local treatment of the lesion renders the outlook more serious.

Prophylaxis.—This is important, and should be carried out by a most rigid disinfection of hides, hair, and rags before they are placed in the hands of workmen. Those handling infected material should have the arms and neck covered, and wear gloves. Wounds in such workers should be promptly disinfected. Animals may be immunized against the disease and Pasteur's method of vaccination has been employed in France with good results. The immunity is lost within a year in nearly 50 per cent. of the animals.

Treatment.—In the cutaneous form, the local lesion should be left alone, as surgical treatment may spread the infection. The part should be kept absolutely at rest, without any dressing and exposed to the air. The anti-anthrax serum should be injected around the area in amounts of 10 to 15 c. c. every four hours. The general treatment should be that of an acute infection. In malignant forms, particularly the intestinal cases, little can be done. Active purgatives may be given at the outset, so as to remove the infecting material. The anti-anthrax serum has given good results and should be given except in mild cases. An initial dose of 100 to 150 c. c. is given intravenously with the usual precautions and repeated every six to eight hours for one or two days depending on the condition. The use of normal bovine serum

(20-30 c. c. heated twice for half an hour to 56° C.) intravenously appears to give good results.

XX. LEPROSY

Definition.—A chronic infectious disease caused by *Bacillus lepræ*, characterized by the presence of tubercular nodules in the skin and mucous membranes (tubercular leprosy) or by changes in the nerves (anæsthetic leprosy). At first these forms may be separate, but ultimately are combined, and in the characteristic tubercular form there are disturbances of sensation.

History.—The disease appears to have prevailed in Egypt even so far back as three or four thousand years B. C. The Hebrew writers make many references to it, but, as is evident from the description in Leviticus, different forms of skin disease were embraced under the term leprosy. Both in India and China the affection was known before the Christian era. The old Greek and Roman physicians were familiar with its manifestations. Evidence of a pre-Columbian existence of leprosy in America has been sought in the old pieces of Peruvian pottery representing deformities suggestive of this disease, but Ashmead denies their significance. Throughout the Middle Ages leprosy prevailed extensively in Europe, largely spread by the crusades, and the number of leper asylums has been estimated as at least 20,000. During the sixteenth century it gradually declined.

Geographical Distribution.—In Europe leprosy prevails in Iceland, Norway and Sweden, parts of Russia, particularly about Dorpat, Riga, and the Caucasus, and in certain provinces of Spain and Portugal. In Great Britain about 500 recognized cases. In Canada there are a few lepers in New Brunswick and in British Columbia (nearly all Chinese). The number has gradually lessened. The disease appears to have been imported from Normandy about the end of the eighteenth century.

Leprosy is endemic in the West India Islands and also occurs in Mexico. In the Sandwich Islands it spread rapidly after 1860, and strenuous attempts have been made to stamp it out by segregating all lepers on the island of Molokai. In British India there are a large number of lepers. In China leprosy prevails extensively and in Africa it has increased rapidly. In Australia, New Zealand, and the Australasian islands it also prevails, chiefly among the Chinese. It occurs both in Central and South America. It is estimated that there are about 3,000,000 lepers in the world.

Etiology.—*Bacillus lepræ*, discovered by Hansen, of Bergen, is universally recognized as the cause of the disease. It has many points of resemblance to the tubercle bacillus, but can be readily differentiated. Some workers claim to have cultivated the organism but there is considerable doubt as to this, as also regarding the success of inoculation experiments.

MODES OF INFECTION.—(a) *Inoculation.*—While it is highly probable that leprosy may be contracted by accidental inoculation, the experimental evidence is inconclusive. With one possible exception, negative results have followed the attempts to reproduce the disease in man. The Hawaiian convict, under sentence of death, who was inoculated on September 30, 1884, by Arning, four weeks later had rheumatoid pains and gradual painful swelling of the

ulnar and median nerves. The neuritis gradually subsided, but a small lepra tubercle developed at the site of the inoculation. In 1887 the disease was manifest, and the man died of it six years after inoculation. The case is not regarded as conclusive, as he had leprous relatives and lived in a leprous country. Insects may take up the bacilli.

(b) *Heredity*.—For years it was thought that the disease was transmitted from parent to child, but the general opinion is now decidedly against this view. The possibility of its transmission cannot be denied, and in this respect leprosy and tuberculosis occupy very much the same position, though men with very wide experience have never seen a new-born leper. The youngest cases are rarely under three or four years of age.

(c) *By Infection*.—The bacilli are given off from the open sores; they are found in the saliva and expectoration of patients with leprous lesions in the mouth and throat, and occur in large numbers in the nasal secretion. Sticker found in 153 lepers, subjects of both forms of the disease, bacilli in the nasal secretion in 128, and herein, he thinks, lies the chief source of danger. Schaffer collected lepra bacilli on clean slides placed on tables and floors near to lepers whom he had caused to read aloud. The bacilli have also been isolated from the urine and the milk of patients. It seems probable that they may enter the body through the mucous membranes and by abrasions of the skin. Sticker believes that the initial lesion is in an ulcer above the cartilaginous part of the nasal septum. One of the most striking examples of the infectiousness of leprosy is the following: "In 1860, a girl who had hitherto lived at Holstfershof, where no leprosy existed, married and went to live at Tarwast with her mother-in-law, who was a leper. She remained healthy, but her three children (1, 2, 3) became leprous, as also her younger sister (4), who came on a visit to Tarwast and slept with the children. The younger sister developed leprosy after returning to Holstfershof. At the latter place a man (5), fifty-two years old, who married one of the 'younger sister's' children, acquired leprosy; also a relative (6), thirty-six years old, a tailor by occupation, who frequented the house, and his wife (7), who came from a place where no leprosy existed." There is evidence that the disease may spread through infected clothing, and the high percentage of washerwomen among lepers is suggestive.

CONDITIONS INFLUENCING INFECTION.—The disease attacks persons of all ages but infection is rare after the age of thirty. Evidently the closest and most intimate contact is essential. The doctors, nurses, and Sisters of Charity who care for the patients are very rarely attacked. In the lazaretto at Tracadie not one of the Sisters who have so faithfully nursed the lepers has contracted the disease. Father Damien, in the Sandwich Islands, and Father Boblioli, in New Orleans, both fell victims in the discharge of their priestly duties.

Morbid Anatomy.—The leprosy tubercles consist of granulomatous tissue made up of cells of various sizes in a connective-tissue matrix. The bacilli in extraordinary numbers lie partly between and partly in the cells. The process gradually involves the skin, giving rise to tuberculous outgrowths with intervening areas of ulceration or cicatrization, which in the face may gradually produce the so-called *facies leontina*. The mucous membranes, particularly the conjunctiva, the cornea, and the larynx, may gradually be involved. In many cases deep ulcers form which result in extensive loss of substance

or loss of fingers or toes, the so-called *lepra mutilans*. In anæsthetic leprosy there is a peripheral *neuritis* due to the development of the bacilli in the nerve-fibres. Indeed, this involvement of the nerves plays a primary part in the etiology of many of the important features, particularly the trophic changes in the skin and the disturbances of sensation.

Clinical Forms.—(a) **TUBERCULAR LEPROSY.**—Prior to the appearance of the nodules there are areas of cutaneous erythema which may be sharply defined and often hyperæsthetic. This is sometimes known as *macular* leprosy. The affected spots in time become pigmented. In some instances this superficial change continues without the development of nodules, the areas become anæsthetic, the pigment gradually disappears, and the skin gets perfectly white—the *lepra alba*. In the early stage there may be a patchy erythema with slight swelling of the skin. The nodules or tubercles appear, sometimes after recurrences of the rash, and may be fairly general. They may gradually disappear but often break down and form ulcers which may involve large areas. There are recurring attacks of irregular fever. The eyelashes and eyebrows and the hairs on the face fall out. The mucous membranes finally become involved, particularly in the mouth, throat, and larynx; the voice becomes harsh and finally aphonic. Death may result from the laryngeal complications and pneumonia, but usually from cachexia after an average period of ten years. The conjunctivæ are frequently attacked, and the sight is lost by a leprous keratitis.

(b) **ANÆSTHETIC LEPROSY.**—This form has, in characteristic cases, no external resemblance to the other variety. It usually begins with pains in the limbs and areas of hyperæsthesia or numbness. Maculæ appear upon the trunk and extremities, and after persisting for a variable time gradually disappear, leaving areas of anæsthesia, but the loss of sensation may come on independently of the outbreak of maculæ. Trophic changes may appear very early. The nerve-trunks, where superficial, may be felt to be large and nodular. The trophic disturbances are usually marked. Pemphigus-like bullæ develop in the affected areas, which break and leave ulcers which may be very destructive. The fingers and toes are liable to contractures and to necrosis, so that in chronic cases the phalanges are lost. The course of anæsthetic leprosy is extraordinarily chronic and may persist for years without leading to much deformity. We knew a prominent clergyman who had anæsthetic leprosy for more than thirty years, which did not seriously interfere with his usefulness, and not in the slightest with his career.

Prognosis.—The outlook for recovery is improved by modern treatment. Lepers usually die of tuberculosis, nephritis or sepsis, rarely of leprosy alone. With involvement of the larynx and generally in the nodular form, the prognosis is more serious.

Diagnosis.—Even in the early stage the dusky erythematous maculæ with hyperæsthesia or areas of anæsthesia are very characteristic. In an advanced grade neither the tubercular nor anæsthetic form is likely to be mistaken. Lupus and syphilis may cause difficulty in the nodular form, and syringomyelia, neuritis and Raynaud's disease in the anæsthetic form. The finding of lepra bacilli in the nasal secretion and the study of a nodule are definite.

Treatment.—The Finsen light, X-rays, and radium do good to the local lesions. Chaulmoogra oil has been extensively used. Heiser advises chaul-

moogra oil 60 c. c., camphorated oil 60 c. c., and resorcin 4 gm.; this is sterilized and 1 c. c. given subcutaneously once a week. The dose is gradually increased to 3 c. c. Rogers advises the intravenous injection of gynocardate of soda (prepared from the fatty acids of chaulmoogra oil) gr. 1/10 to 4/5 (0.006 to 0.05 gm.), in a 2 per cent. saline solution and 0.5 per cent. phenol. Several different preparations from chaulmoogra oil are used. Ultra-violet light treatment is useful for nerve pains and is given over areas of necrosis and induration.

Segregation should be compulsory except when there is ample provision for the complete isolation and proper care of the patient.

XXI. TUBERCULOSIS

I. GENERAL ETIOLOGY AND MORBID ANATOMY

Definition.—An infection caused by *Bacillus tuberculosis*, the lesions of which are characterized by nodular bodies, tubercles, and diffuse infiltrations, which either undergo caseation, necrosis, and ulceration, or heal with sclerosis and calcification.

The very varied clinical features depend upon the organ involved, the intensity of the infection, and the degree of resistance offered by the body.

History.—The Greek physicians made many observations upon the clinical features of pulmonary tuberculosis, and our description of the symptoms and of the consumptive "type" dates from Hippocrates. Galen recognized its infectious nature. In the seventeenth century F. Sylvius indicated the connection between the tuberculous nodule and phthisis, and Richard Morton, a friend and contemporary of Sydenham, wrote (1689) the first modern treatise on the subject, in which the clinical side of the disease was well considered. He regarded it as contagious. Pierre Desault, William Stark, and Matthew Baillie laid the foundation of our knowledge of the coarse characters of tubercle as the anatomical basis of tuberculosis. Our real knowledge of the disease is a nineteenth century contribution, beginning with the work of Bayle on the structure of the tubercle and on its identity in the widely distributed lesions. With the *Traité d'Auscultation Médiate* (1819) Laennec laid the foundation not only of our modern knowledge of tuberculosis, but of modern clinical medicine. This work (easily to be had in an English translation) should be read from cover to cover by every young doctor, and, when possible, by every senior student. The unity of the forms of the tubercle—the miliary granule, the infiltration, and the caseous mass—was recognized, and for the first time physical signs and anatomical features were correlated, and the course of the disease carefully studied. Virchow led a battle against the unity of tuberculous lesions, and held that the products of any simple inflammation might become caseous, and that the ordinary so-called catarrhal pneumonia might terminate in phthisis.

The infectiousness of the disease, a belief in which had long been held by individuals, and was widely spread in certain countries—as in Italy—was emphasized and confirmed by the brilliant work of Villemin, who first placed the infective nature of the disease on a solid experimental basis. There

is nothing more masterly in the literature of experimental medicine than his work. Then came the demonstration by Robert Koch (in 1882) of the *Bacillus tuberculosis*. The preliminary article in the Berliner klin. Wochenschrift (1882) and the more complete work (Mitteilungen a. d. k. Gesundheitsamte, Bd. 2) should be studied by all who wish to appreciate the value of scientific methods. The thoroughness of Koch's work is manifested by the fact that, in the years that have elapsed, the innumerable workers have amplified and extended, but in no way essentially modified his original position.

Distribution.—The disease is widely spread zoologically.

(a) IN ANIMALS.—Of animals the cold-blooded are rarely affected. In birds the disease is not uncommon, particularly in fowls, but there are minor differences between the avian and mammalian forms. In the domestic animals tuberculosis is a common disease, particularly in cattle. In sheep, goats, and horses it is rare. In pigs it is not uncommon in certain parts of Europe. Cats and dogs are not prone to the disease. In monkeys in confinement it is very common. The most important single fact in the distribution of the disease in animals is its widespread prevalence in bovines, from which nearly all the milk and a large proportion of our meat are derived.

(b) IN MAN.—Tuberculosis is his most universal scourge, well deserving the epithet bestowed upon it by Bunyan of the "Captain of the Men of Death." It is estimated that at least one-eighth of all deaths are due to it. In England and Wales there were 36,623 deaths from all forms of tuberculosis in 1928. In the United States it is responsible for about 8 per cent. of all deaths. The rate in the registration areas was 201.9 per 100,000 in 1900 and 86.6 in 1925. There has been a remarkable reduction in England in the death-rate within the past fifty years.

In London the death-rate from pulmonary tuberculosis declined 33 per cent. between 1901 and 1910, and other forms of tuberculosis show a similar fall. To a less striking degree, but practically everywhere in the civilized world, there has been a reduction in the death-rate—the most encouraging feature of modern sanitation. To what is this to be attributed? *First.* To the improved social condition of the people, better housing, better food, better habits and better working conditions. The falling death-rate began before the present campaign against the disease. *Secondly.* The education of the people, which has made great strides, and a large proportion are striving to lead hygienic lives. There are less drunkenness, less overcrowding, better air, and better food. The habit of spitting in public has been checked and the seeds of the disease are not spread so broadcast. Child welfare work with its education of parents and children in matters of health and the attention given to under-nourished children have had a good influence. *Thirdly.* Segregation has done much to protect the healthy from the sick and a larger number of advanced cases are in hospitals. *Fourthly.* The patients are seen earlier and the condition is recognized before it is hopeless. In a larger number of persons with pulmonary disease the diagnosis is made at a stage when complete healing is possible. The two important elements then are, fewer seeds, more stony soil. The economic loss from tuberculosis is enormous. It is estimated that in many communities, about 1 per cent. of the population has active tuberculosis and another 1 per cent. has arrested disease. There are approximately 9 active cases for each death per annum. The cost of death

and sickness from tuberculosis each year is hundreds of millions of dollars! Tuberculosis shortens the average duration of life by two and a half years.

Etiology: the *Bacillus tuberculosis*.—(a) **THE SEED.**—The *Bacillus tuberculosis* is a minute rod-shaped organism slightly bent or curved, with an average length of from 3 to 4 μ . When stained it may present a beaded appearance. Aberrant forms are not uncommon, i. e., long filaments or branched forms. It stains in a characteristic way with aniline dyes, is “acid fast,” and in cultures the growth is distinctive. The virulence of the individual strains varies, a factor of great importance in all specific infections.

Specific varieties are recognized. The avian form has well-marked peculiarities, but the great point of discussion has been the relation of the bacillus causing human to that which causes bovine tuberculosis. Differences in the character of the tubercles of these two classes had long been recognized, and Theobald Smith pointed out special differences between the human and the bovine bacilli. The matter was brought to a focus in 1901 by Koch's statement that the bacilli of bovine tuberculosis did not cause human tuberculosis, and *vice versa*. The question has been submitted to the test and it is generally recognized that there are differences between the two forms. The report of the English commission confirms the view that the bovine organism is capable of producing the disease in man, in whom it may often be recognized as a special form.

In the Body.—The bacilli are found in all tuberculous lesions, particularly in those actively growing, but in the chronic disease of the lymph-glands and of the joints they are scanty. In all caseous foci they are few in number. In the sputum in pulmonary tuberculosis they may be present in countless myriads. They are sometimes found in the blood, particularly in cases of miliary tuberculosis, and recent work suggests that this is common in open cases of pulmonary tuberculosis.

Outside the Body.—Tubercle bacilli are widely scattered and found in varying numbers wherever human beings are crowded together. There are two chief sources—the expectoration of persons with advanced disease of the lungs and the milk of tuberculous cows.

From a patient in the Johns Hopkins Hospital, with moderately advanced disease, Nuttall estimated that from $1\frac{1}{2}$ to 4 billions of bacilli were thrown off each twenty-four hours. Allowed to dry, the sputum becomes dust and is distributed far and wide. Experiments have shown the presence of the bacilli in dust samples from hospital wards, from public buildings, streets, railway carriages, and various localities. So widely spread are the bacilli that in cities at least few individuals pass a week without affording opportunity for their lodgment, usually in the throat or air passages, inhaled with dust. They may readily contaminate food. The hands of tuberculous subjects are almost always contaminated. From the street, tuberculous sputum may be brought into the house on shoes, on the long skirts of women, on the hair of dogs, etc. It is interesting to note that in some of the places most frequented by tuberculous subjects, e. g., the sanatoria, the dust (as shown by experiments at Saranac) may be free from bacilli.

Bovine bacilli are distributed by means of the milk, rarely by the flesh, and still more rarely by contact with the animals. A proportion of all cases of infection in childhood are with this variety. A study by Park and Krum-

wiede showed that bovine tuberculosis is practically negligible in adults but in young children may cause about 10 per cent. of the deaths from tuberculosis when cattle are not inspected or the milk pasteurized.

So widely spread everywhere is the seed, that the soil, the conditions suitable for its growth, is practically of equal moment.

(b) THE SOIL.—Many years ago the senior author drew the parallel between infection in tuberculosis and the parable of the sower, which though now somewhat hackneyed illustrates in an effective way the importance of the nature of the ground upon which the seed falls. *"Some seeds fell by the wayside and the fowls of the air came and devoured them up."* These are the bacilli scattered broadcast outside the body, an immense majority of which die. *"Some fell upon stony places."* These are the bacilli that find lodgment in many of us, perhaps, with the production of a small focus, but nothing comes of it; they wither away "because they have no root." *"Some fell among thorns, and the thorns sprang up and choked them."* This represents the cases of tuberculosis, latent or active, in which the seed finds the soil suitable and grows, but the conditions are not favorable, as the thorns, representing the protecting force of the body, get the better in the struggle. *"But others fell on good ground and sprang up and bare fruit an hundredfold."* Of this fourth group were the 36,623 who died of the disease in 1928 in England—the soil suitable, the protecting forces feeble.

What makes a good soil? Fortunately the human body is not a very good culture medium for the tubercle bacillus. The adult human individual in normal health seems to be practically immune to natural infection (Baldwin). And yet about one-eighth of the human race dies of tuberculosis, but a large proportion of all individuals become infected before reaching adult life and never have the disease. The studies of Naegli, Burkhardt, and others show that in fully 90 per cent. of the bodies of city-dwellers who have died of disease other than tuberculosis small tuberculous lesions are present. This is probably too high an estimate for England or the United States. Franz has shown that over 60 per cent. of healthy young adults react to the subcutaneous tuberculin test. Using more delicate tuberculin tests, it is found that nearly all adults react, and according to Hamburger over 90 per cent. of children are infected before reaching the twelfth year of life. This means, of course, that in a small proportion of those upon whom the seed falls is the soil suitable for active growth—only a natural immunity keeps the race alive.

What this suitable soil is has been the subject of much discussion. From the time of Hippocrates the profession has recognized a tuberculous habitus, which has been variously described as disposition, diathesis, dyscrasia, temperament, constitution, or by the German word "Anlage." These terms are not always regarded as interchangeable, but here for practical purposes Ribbert's definition suffices, that a disposition is "that peculiarity in the organism which allows of the effective working of the exciting causes of a disease." Manifestly, such a disposition or constitution of the body may be inherited or acquired. Pearson concludes that "the diathesis of pulmonary tuberculosis is certainly inherited, and the intensity of the inheritance is sensibly the same as that of any normal physical character yet investigated in man. Infection probably plays a necessary part, but in the artisan classes of the urban populations of this country (England) it is doubtful if their members can

escape the risks of infection, except by the absence of diathesis—i. e., the inheritance of what amounts to a counter-disposition.”

Hippocrates defined the *habitus phthisicus* in the following words: “The form of body peculiar to subjects of phthisical complaints was the smooth, the whitish, that resembled the lentil; the reddish, the blue-eyed, the leucophlegmatic, and that with the scapulæ having the appearance of wings.” The so-called scrofulous type has broad coarse features, opaque skin, large thick bones, and heavy figure.

Acquired disposition may arise through a lowering of the resistance of the body forces. Dwellers in cities in the dark, close alleys, and tenement houses, workers in cellars and ill-ventilated rooms, persons addicted to drink, are much more prone to the disease. The influence of environment was never better demonstrated than in the well-known experiment of Trudeau, who found that rabbits inoculated with tuberculosis if confined in a dark, damp place, without sunlight and fresh air, rapidly succumbed, while others treated in the same way, but allowed to run wild, either recovered or showed very slight lesions. The occupants of prisons, asylums, and poorhouses, too often, indeed, in barracks and large workshops, are in the position of Trudeau’s rabbits in the cellar, and under the conditions most favorable to foster the development of the bacilli which have lodged in their tissues.

No age is exempt. The disease is met with in the suckling and in the octogenarian, but fatal tuberculosis is, as Hippocrates pointed out, more common between the eighteenth and thirty-fifth year. The influence of *sex* is very slight. On the other hand the influence of *race* is important. It is a very fatal disease in negroes, particularly in the United States, and in the North American Indians, among whom in 1915, 35 per cent. of the deaths were due to tuberculosis. The *Irish*, both at home and in the United States, are more prone to the disease than other European races. The *Jews* everywhere have a low mortality from tuberculosis.

Occupation has an influence, in so far as insanitary surroundings, exposure to dust, close confinement, long, irregular hours, and low wages, favor the prevalence of the disease. *Economic factors* are important and the social and home conditions should be considered in estimating the influence of occupation. Certain local conditions influence the soil very greatly. Catarrh of the respiratory passages appears to lower the resistance and favor the conditions which enable the bacilli to enter and grow in the tissues. It is doubtful whether the specific fevers predispose to tuberculosis; although any lowering disease may do so, but in such cases it is often not a fresh infection, but the blazing of a smouldering fire. The soil of *diabetes* is favorable to the growth of tubercle bacilli. Many *chronic affections* lower the resistance and it is notorious in hospital practice how often the fatal event in arteriosclerosis, cirrhosis of the liver, etc., is a terminal acute tuberculosis. There is no evidence that being gassed in war favors tuberculous infection.

Trauma, as for example a blow on the chest, injury to the knee, a blow upon the head, may be followed by local tuberculosis. The injured part for a time is a *locus minoris resistentiæ*, and the bacilli already present grow in the favorable conditions caused by the injury.

(c) SPECIFIC REACTIONS OF THE BACILLI.—In its growth the bacillus so far as we know does not form soluble toxins, at least not in the cultures. It

causes (1) a local tissue reaction which results in the formation of a new growth, the tubercle; (2) changes in the immunity reactions of the body fluids. The local tissue reactions will be considered later; here we may speak of the phenomena grouped under the term immunity.

(1) *Tuberculin Reaction*.—An animal inoculated subcutaneously with tubercle bacilli, or with dead cultures, has a local reaction associated with the formation of a tubercle; the neighboring lymph glands become involved, and in susceptible animals the disease generalizes and causes death if living organisms were inoculated. Koch found that if to a guinea-pig with a subcutaneous focus of tuberculosis so caused a second injection of the bacillus was given, healing occurred in the primary nodule, and the animal did not die. Upon these facts his tuberculin treatment was based. Tuberculin is the sterilized filtered concentrate of glycerine bouillon cultures of the tubercle bacillus ("old" tuberculin, O.T.). If into a healthy person .025 c. c. of original tuberculin is injected, there is a slight fever with a feeling of uneasiness which passes off in from twelve to twenty-four hours. If into an individual with a focus of tuberculosis doses of .015 c. c. of tuberculin are injected subcutaneously, there is an active *focal* reaction about the tuberculous lesion and a *constitutional* reaction (fever, general pains, etc.). This process, known as the "tuberculin reaction," is not often used now for diagnosis. The reaction may be local, focal or constitutional. The skin reactions are the safest because the reaction is local. The chief methods are the intracutaneous of Mantoux and the cutaneous of Pirquet.

Intracutaneous Test of Mantoux.—The inner surface of the forearm is cleaned with alcohol and ether; the skin is drawn tight and the diluted tuberculin (various dilutions are employed, 0.1 c. c. of the solution containing 1.0 mgm., 0.1 mgm., or 0.01 mgm. of tuberculin) is injected through a fine needle *into*, not *under*, the skin. The weakest solution is used first. A control test is made by injecting sterile glycerine bouillon of the same concentration. A positive reaction shows hyperæmia and swelling, with vesiculation in severe reactions. It appears in from 6 to 8 hours, reaches a maximum in 1 to 2 days and disappears in 6 to 8 days.

In the *cutaneous* test of Pirquet a small abrasion is made on the inner surface of the forearm and a drop of old tuberculin is placed on it. A positive reaction appears within 48 hours, shows a papule surrounded by a hyperæmic zone. The size of the papule and the area of hyperæmia vary. A faint brownish pigmentation may persist for some weeks. A control test is done with glycerine bouillon solution.

(2) *Immunity Changes*.—In an infected person certain changes occur in the blood serum, depending upon the development of so-called antibodies, the presence of which may be demonstrated by the method of complement fixation; and the serum also contains agglutinins which possess an agglutinating action on the tubercle bacilli. Either directly themselves or through the toxic products there are brought into play certain cellular and humoral reactions which are capable of destroying the infecting agents or of neutralizing their effects or of limiting their activities. Experimentally in animals, according to the virulence of the organism and the dose, all gradations of symptoms may be produced, from the slightest local reaction to the profoundest septicæmia with high fever and death. In a local tuberculous infection, such as happens

to the great majority of us at some time in our lives, happily the protective mechanism suffices to localize and limit the invaders. It may amount only to a skirmish, such as is constantly going on at the frontiers of a great empire, but if the local infection is more virulent, or becomes wider spread, the products of the growth of the bacilli or the bacilli themselves enter the circulation, an auto-inoculation, in which case the general metabolism is disturbed, fever is produced, and antibodies are formed. The immunity in adult life in many cases is probably due to a latent infection in early life which was successfully resisted.

Allergy.—The primary infection occurs in tissues which have no specific defence. As a rule it is so severe that it kills quickly, as is seen in very young children, or so slight that it heals or remains quiescent without symptoms. The tissue response is largely non-inflammatory and the bacilli usually survive at the point of entrance and in the regional lymph nodes. With this changes occur and substances are liberated which pass into the body fluids and render the body cells sensitive to the tubercle bacillus and its protein. In other words, *allergy* is established and the subsequent defence is a specific process. Any further infection occurs in a sensitized individual and so the specific immunizing reactions result. Focal allergic reactions occur whenever bacilli spread to new tissue and vary from hyperæmia to marked exudation. There may be caseation, necrosis, resolutions or fibrosis as a result. Reinfections find allergic tissues and the reaction may be marked. It is evident that reinfections may be from outside or from foci in the patient's body. Such infections probably increase the resistance unless they are too severe for the organism to overcome.

We speak of *productive* and *exudative* lesions but the terms are not always used with the same meaning in the literature. In the productive lesion new tissue is formed, as in the tubercle. In the exudative lesion there is an exudate which infiltrates the normal tissue but does not replace it. If it caseates, the exudate and the elements of the involved tissues are involved. In the tubercle it is the new formed granulation tissue which breaks down. The two lesions may co-exist but one is superimposed on the other. Much of the inflammation in tuberculosis is exudative which may clear by resolution. The shadows seen in lungs after hæmorrhage probably are caused by an exudation due to allergy.

Koch observed a marked difference in the reaction of healthy and tuberculous animals to cutaneous inoculation with tubercle bacilli. In healthy animals the wound closes and for a few days seems to heal, but in from ten to fourteen days a hard nodule appears, which soon breaks down. General infection occurs and the ulcer remains open to the time of the death of the animal. In tuberculous animals an acute inflammatory ulceration occurs on the second or third day after inoculation, but the ulcer heals quickly and permanently, without even the neighboring lymph glands becoming infected.

(d) Modes of Infection.—(1) *Hereditary Transmission*.—In order that the disease could be transmitted by the sperm it would be necessary that the tubercle bacilli should lodge in the individual spermatozoon which fecundates an ovum. The chances that such a thing could occur are extremely small, looking at the subject from a numerical point of view, although we know that

bacilli do occasionally exist in the semen; they become still smaller when we consider that the spermatozoon is made up of nuclear material, which the tubercle bacillus is never known to attack. The possibility of transmission by the ovum must be accepted. Baumgarten was able in one instance to detect the tubercle bacillus in the ovum of a female rabbit which had been artificially fecundated with tuberculous semen.

(2) *Congenital*.—The almost constant method of transmission in congenital tuberculosis is through the blood current, the tubercle bacilli penetrating by the placenta which is usually the seat of tuberculosis. But there are undoubted instances in which, with an apparently sound placenta, both the placental blood and the fetal organs contained tubercle bacilli, although the organs appeared normal. The number of cases of congenital tuberculosis in man is very small; it is more common in cattle.

Latency of the Tubercle Germs.—Baumgarten and his followers assume that tubercle bacilli, present in the new-born child, lie latent in the tissues and subsequently develop when, for some reason or other, the individual resistance is lowered. The small number of congenital cases is against this view. The more modern view is that adult infection is not necessarily derived from childhood infection but may be exogenous. Re-infection in adults tends to be apical in localization and show chronicity.

(3) *Inoculation*.—*Cutaneous*.—The infective nature of tuberculosis was first demonstrated by Villemin, who showed in 1865 that it could be transmitted to animals by inoculation. The experiments of Cohnheim and Salomonsen, who produced tuberculosis in the eyes of guinea-pigs and rabbits by inoculating fresh tubercle into the anterior chamber, confirmed and extended Villemin's observations and paved the way for Koch's announcement. This mode of infection is seen in persons whose occupation brings them in contact with dead bodies or animal products. Demonstrators of morbid anatomy, butchers, and handlers of hides are subject to a local tubercle of the skin, which forms a reddened mass of granulation tissue, usually on the dorsal surface of the hand or a finger. This is the so-called post-mortem wart, the *verruca necrogenica* of Wilks. The proof of its nature is shown by the presence of tubercle bacilli and by inoculation experiments in animals.

In the performance of circumcision children have been accidentally inoculated. Infection in these cases is probably always associated with disease in the operator and occurs in connection with the habit of cleansing the wound by suction. Other means of inoculation are described: as the wearing of earrings, washing the clothes of tuberculous patients, the bite of a tuberculous subject, or a cut by a broken sputum cup of a consumptive; Czerny reported two cases of infection by transplantation of skin.

It has been urged by the opponents of vaccination that tuberculosis may be thus conveyed, but of this there is no evidence. Lupus has originated at the site of vaccination in a few cases (C. Fox, Graham Little). It may be said that inoculation in man plays a trifling rôle in the transmission of tuberculosis.

Mucous membrane inoculation is probably important in childhood through abrasions of the lips, tongue or gums, though a primary focus is not often seen. The open door in the mouth and throat is more often by loss of the protective epithelium due to catarrhal and ulcerative processes.

(4) *Infection in Childhood*.—The special points favoring this are: (a)

The intimate contact between children and parents and other adults in households where tuberculosis exists. (b) The habit of playing about the floor and putting objects in the mouth. (c) The influence of certain infections, but such cases are probably rare. (d) The large place which milk takes in the dietary. (e) The close contact with other children in school. The result may be: (i) Acute tuberculosis and death. (ii) An infection of short duration with slight symptoms and recovery. (iii) A more chronic condition. (iv) Latency of the disease until adult life, when, as the result of lowered resistance by many factors, the infection becomes active.

The typical localization of the primary focus in children is close to the pleura in any part of the lung and rarely at the apex. The associated lymph node involvement is in relation to this parenchymatous focus. The first response to inhalation infection is an exudative lesion but productive lesions follow quickly, perhaps in two or three weeks. If healing of the primary focus occurs it does not show the changes found about an area of re-infection.

(5) *Infection by Inhalation.*—A belief in the contagiousness of pulmonary tuberculosis originated with the early Greek physicians, and persisted among the Latin races. The investigations of Cornet afford conclusive proof that the dust of a room or other locality frequented by patients with pulmonary tuberculosis is infective. The bacilli attached to fine particles of dust are inhaled and gain entrance through the respiratory tract.

Flügge denied that the bacillus-containing dust is the dangerous element in infection. Experimentally he only succeeded in producing the disease when there is some lesion in the respiratory tract. He regarded the danger of infection by dry sputum as slight and held that the infection is chiefly conveyed by the finely divided particles of sputum produced in coughing.

It is well remarked by Cornet, "The consumptive in himself is almost harmless, and only becomes harmful through bad habits." It has been fully shown that the expired air of consumptives is not infective. The virus is contained in the sputum, which when dry is widely disseminated in the form of dust, and constitutes the great medium for the transmission of the disease. Among the points urged in favor of the inhalation view are:

(i) Primary tuberculous lesions are in a majority of all cases connected with the respiratory system. The frequency with which foci are found in the lungs and bronchial glands is extraordinary, and the statistics of the Paris morgue show that a considerable proportion of all persons dying of accident or by suicide present evidences of the disease in these parts. The post-mortem statistics of hospitals show the same widespread prevalence of infection through the air passages. In 125 autopsies at the Foundling Hospital, New York, the bronchial glands were tuberculous in every case. In adults the bronchial glands may be infected and the individual remain in good health.

(ii) The greater prevalence of tuberculosis in institutions in which the residents are confined and restricted in the matter of fresh air and a free open life—conditions which favor, on the one hand, the presence of the bacilli in the atmosphere, and, on the other, lower the resistance of the individual. The investigations of Cornet upon the death-rate among certain religious orders give some striking facts in illustration of this. In a review of 38 cloisters, embracing an average number of 4,028 residents, among 2,099

deaths in twenty-five years, 1,320 (62.88 per cent.) were from tuberculosis. In some cloisters more than three-fourths of the deaths are from this disease, and the mortality in all the residents, up to the fortieth year, is greatly above the average, the increase being due entirely to tuberculosis. The more perfect the hygienic arrangements of an institution, the lower the death rate from tuberculosis. The mortality in prisons is sometimes four times as great as outside. The death-rate from tuberculosis in prisons constitutes from 40 to 50 per cent., and in some countries, over 60 per cent. of the total mortality. Flick studied the distribution of the deaths from tuberculosis in a single city ward in Philadelphia for twenty-five years. His researches go far to show that it is a *house* disease. About 33 per cent. of infected houses had more than one case. There are, however, opposing facts. The statistics of the Brompton Consumption Hospital show that doctors, nurses, and attendants are rarely attacked. Dettweiler claimed that no case of tuberculosis has been contracted among his nurses or attendants at Falkenstein. Among 174 previously healthy sanitarium physicians whose average term of service was three years only two became tuberculous (Sangmann). On the other hand, in the Paris hospitals tuberculosis decimates the attendants.

(iii) Special danger was believed to exist when the contact is very intimate, as between man and wife, but upon the figures of the late Ernest Pope, of Saranac, Karl Pearson bases the following conclusions: (a) There is some sensible but slight infection between married couples; (b) this is largely obscured or forestalled by the fact of infection from outside sources; (c) the liability to the infection depends on the presence of the necessary diathesis; (d) assortative mating probably accounts for at least two-thirds, and infective action not more than one-third of the whole correlation in these cases. There are cases in which this source of infection seems to play a rôle.

(6) *Infection by Ingestion*.—There are two other channels, the tonsils and the intestines, both of great importance.

(i) *Tonsillar Infection*.—The bacilli pass to the glands of the neck and mediastinum, and reach the circulation through the lymph-channels. Or an infected bronchial gland becomes adherent to a branch of the pulmonary artery; if a large number of bacilli escape, miliary tuberculosis follows; if only a small number, they reach the lungs. Through this tonsillar-cervical route bacilli may gain entrance without causing local disease at the portal of entry. In a study of nearly 9,000 cases by Weller active tuberculosis of the tonsils was found in 2.35 per cent. The age varied from 2 to 59 years. Many of the individuals with tuberculous tonsils seemed in good health. There is nothing characteristic in the appearance of the gland. There are several forms: (1) Infection of the crypts with sub-mucous tubercles; this is the most common and is probably primary. (2) Ulcerative lesions which may follow the first form; (3) A diffuse miliary form, probably hæmatogenous; (4) Mixed cases. Involvement of the glands was not always present.

(ii) *Intestinal Infection*.—Behring announced in 1903 that pulmonary tuberculosis could be induced through intestinal infection, and further maintained that milk fed to infants was the chief cause of tuberculosis in adults, the infection remaining latent. Behring's first contention was supported by Ravenel and others, who produced pulmonary tuberculosis in animals by feeding experiments, and it was demonstrated that the intestinal surface itself

might remain intact. This does away with the objection raised by Koch that, if infection through the milk of tuberculous cattle is common, primary intestinal tuberculosis should be more frequent, whereas in ten years among 3,104 cases of tuberculosis in children there were only 16 of primary bowel infection. Experiments have shown in a striking manner how the lungs act as filters for particles absorbed from the intestines. Vansteenbergh and Grysez produced anthracosis of the lungs by introducing china-ink emulsion directly into the stomach (see Anthracosis). They found a remarkable difference in young and adult guinea-pigs; in the former the carbon particles were filtered out by the mesenteric glands, while the lungs remained free; in the latter the glands were unaffected, but the lungs were carbonized. Calmette and Guérin have shown how easily the lungs may be infected through the intestinal route without leaving the slightest trace of disease of the bowel itself. Behring's view of the importance of infection through the intestinal route has thus received support, and many go so far as to maintain that a majority of all cases of tuberculosis originate in this manner. The truth is that this ubiquitous bacillus is not particular, and gains entrance through either portal, preferring the throat and intestines in childhood, the bronchi and lungs in adults. The important matter for the individual is the nature of the soil on which it falls.

Milk is a common source of intestinal infection. The ordinary commercial pasteurization, as now done, kills tubercle bacilli and is responsible for the great decrease in tuberculous adenitis.

The flesh of tuberculous animals is rarely dangerous.

(7) *Re-infection*.—This is not uncommon in adult life but its frequency is difficult to state. Repeated slight infections may be important.

Morbid Anatomy.—(a) DISTRIBUTION OF THE TUBERCLES IN THE BODY.—The primary localization of the tubercle bacillus in the vast majority of cases, if not in all, is in the lymphatic structures; involvement of the lungs is secondary. Clinically in adults, the lungs may be regarded as the seat of election; in children, the lymph-nodes, bones, and joints. In 1,000 autopsies there were 275 cases with tuberculous lesions. With but two or three exceptions the lungs were affected. The distribution in the other organs was as follows: Pericardium, 7; peritoneum, 36; brain, 31; spleen, 23; liver, 12; kidneys, 32; intestines, 65; heart, 4; and generative organs, 8. Among 1287 tuberculous surgical patients at the Würzburg clinic, the distribution of lesions was: Bones and joints, 1,037; lymph-nodes, 196; skin and connective tissues, 77; mucous membranes, 10; genito-urinary organs, 20.

(b) THE CHANGES PRODUCED BY THE TUBERCLE BACILLI.—*The Nodular Tubercle*.—A "tubercle" *presents in its early formation nothing distinctive or peculiar, either in its components or in their arrangement*. Identical structures are produced by other parasites, such as actinomycetes.

The following changes occur in the evolution of a tubercle:

(1) The tubercle bacilli multiply and disseminate in the surrounding tissues, partly by growth, partly in the lymph currents.

(2) The fixed cells, especially those of connective tissue and the endothelium of the capillaries, multiply and form rounded, cuboidal, or polygonal bodies with vesicular nuclei—the *epithelioid cells*—inside some of which the bacilli are soon seen.

(3) Leucocytes, chiefly polynuclear, migrate in numbers and accumulate about the focus of infection. They do not survive. Many undergo rapid destruction. Later, as the little tubercle grows, the leucocytes are chiefly of the mononuclear variety, which do not undergo the rapid degeneration of the polynuclear forms.

(4) A reticulum of fibres is formed by the fibrillation and rarefaction of the connective-tissue matrix. This is most apparent, as a rule, at the margin.

(5) In some, but not all, tubercles giant cells are formed by an increase in the protoplasm and in the nuclei of an individual cell, or possibly by the fusion of several cells. The giant cells seem to be in inverse ratio to the number and virulence of the bacilli.

(c) THE DEGENERATION OF TUBERCLE.—(1) *Caseation*.—At the central part of the growth, owing to the direct action of the bacilli or their products, a process of coagulation necrosis goes on in the cells, which lose their outline, become irregular, no longer take stains, and are finally converted into a homogeneous, structureless substance. This may be due to the blood supply being cut off or to the toxins of the tubercle bacillus. Proceeding from the centre outward, the tubercle may be gradually converted into a yellowish-gray body, in which the bacilli are still abundant. No blood vessels are found in them. Aggregated together these form cheesy masses which may undergo softening, fibroid limitation (encapsulation), or calcification.

(2) *Sclerosis*.—With the necrosis of the cell elements at the centre of the tubercle, hyaline transformation proceeds, together with great increase in the fibroid elements; so that the tubercle is converted into a firm, hard structure. Often the change is rather of a fibro-caseous nature; but the sclerosis predominates. In some situations, as in the peritoneum, this seems to be the natural transformation and it is by no means rare in the lungs.

In all tubercles two processes go on: the one—caseation—destructive and dangerous; and the other—sclerosis—conservative and healing. The ultimate result in a given case depends upon the capabilities of the body to fight the invaders. There are tissue-soils in which the bacilli are, in all probability, killed at once. There are others in which a lodgment is gained and more or less damage done, but finally the day is with the protecting forces. Thirdly, there are tissue-soils in which the bacilli grow luxuriantly, caseation and softening, not limitation and sclerosis, prevail, and the day is with the invaders.

The action of the bacilli injected directly into the blood-vessels illustrates many points in the histology and pathology of tuberculosis. If into the vein of a rabbit a pure culture of the bacilli is injected, the microbes accumulate chiefly in the liver and spleen. The animal dies usually within two weeks, and the organs apparently show no trace of tubercles. Microscopically, in both spleen and liver the young tubercles in process of formation are very numerous, and karyokinesis is going on in the liver-cells. After an injection of a more dilute culture, or one of less virulence, instead of dying within a fortnight the animal survives for five or six weeks, by which time the tubercles are apparent in the spleen and liver, and often in the other organs.

(d) THE DIFFUSE EXUDATIVE LESION.—This is most frequently seen in the lungs and results from the fusion of many small foci of infection—so small indeed that they may not be visible to the naked eye, but which histologically are seen to be composed of scattered centres, surrounded by areas

in which the air-cells are filled with the products of exudation and of the proliferation of the alveolar epithelium. Caseation takes place, usually in small groups of lobules, occasionally in an entire lobe, or even the greater part of a lung. This inflammatory response is the result of fresh areas of infection in sensitized tissues. In the early stage of the process, the tissue has a gray gelatinous appearance, the *gray infiltration* of Laennec. These cells accumulate and undergo coagulation necrosis, forming areas of caseation, the *infiltration tuberculeuse jaune* of Laennec, the *scrofulous* or *cheesy pneumonia* of later writers. There may also be a diffuse infiltration and caseation without any special foci, a widespread tuberculous pneumonia induced by the bacilli.

The essential feature of the allergic reaction is exudation, appearing as inflammation in tissues and effusion in serous spaces. The process may develop rapidly. Tubercles present at the time of re-infection may also show an acute inflammatory reaction and a stimulation of fibrosis.

(e) SECONDARY INFLAMMATORY PROCESSES.—(1) The irritation caused by the bacilli produces an inflammation which may be limited to exudation of leucocytes and serum, but may also be much more extensive, and vary with changing conditions. We find, for example, about the smaller tubercles in the lungs, *pneumonia*—either catarrhal or fibrinous—proliferation of the connective-tissue elements in the septa (which also become infiltrated with round cells), and changes in the blood and lymph-vessels.

(2) In processes of minor intensity the inflammation is of the slow reactive nature, which results in the production of a cicatricial connective tissue which limits and restricts the development of the tubercles and is the essential conservative element in the disease. It is to be remembered that in chronic pulmonary tuberculosis much of the fibroid tissue which is present is not in any way associated with the action of the bacilli. Persistent infection from the upper respiratory tract, as from sinusitis, may be responsible for fibroid changes in the same way as in the non-tuberculous.

(3) *Suppuration*.—Do the bacilli themselves induce suppuration? In so-called cold tuberculous abscess the material is not histologically pus, but a *débris* consisting of broken-down cells and cheesy material. It is moreover sterile—that is, does not contain the usual pus organisms. The products of the tubercle bacilli are probably able to induce suppuration, as in the joint and bone tuberculosis pus is frequently produced, although this may be due to a mixed infection. Tuberculin is one of the best agents for the production of experimental suppuration. In tuberculosis of the lungs the suppuration is largely the result of an infection with pus organisms.

II. ACUTE MILIARY TUBERCULOSIS

The modern knowledge of this remarkable form dates from the statement of Buhl (1856), that miliary tuberculosis is a specific infection dependent on the presence in the body of an unencapsulated yellow tubercle, or a tuberculous cavity in the lung; and that it bears the same relation to the primary lesion as pyæmia does to a focus of suppuration.

Carl Weigert established the truth of this brilliant conception by demonstrating the association of miliary tuberculosis with tuberculosis of the blood-vessels. There are two groups of *vessel tubercle*—the tuberculous periangitis

in which there is invasion of the adventitia, and the endangitis in which the tubercles start in the intima. The parts most frequently affected are the pulmonary veins and the thoracic duct, less often the jugular vein, the supra-renal and the vena cava superior, and the sinuses of the dura mater, the aorta, and the endocardium. To the branches of the pulmonary veins it is not uncommon to find caseous glands adherent, penetrating the walls and showing a growth of miliary tubercles in the intima. A special interest belongs to tuberculosis of the thoracic duct, first accurately described by Sir Astley Cooper. Benda in a series of 19 cases of vessel tuberculosis found in many instances an enormous number of bacilli, particularly in the caseous tubercles of the thoracic duct.

The bacilli do not increase in the blood, but settle in the different organs, producing a generalized tuberculosis, of which Weigert recognized three types or grades: I. The acute general miliary tuberculosis, in which the various organs of the body are stuffed with miliary and submiliary nodules. II. A second form characterized by a small number of tubercles in one or many organs. III. The occurrence of numerous tuberculous foci widely spread throughout the body, but in a more chronic form; the tubercles are larger and many are caseous. It is the chronic generalized tuberculosis of children. Transitional forms between these groups occur. In the first variety, which we are here considering, there is an eruption into the circulation of an enormous number of bacilli. Benda suggests in explanation of the profound toxæmia seen in certain cases (the typhoid form) that in addition the blood is surcharged with toxins from a large caseous focus which has eroded a vessel.

Clinical Forms

The cases may be grouped into those with the symptoms of an acute general infection—the typhoid form; cases in which pulmonary symptoms predominate; and cases in which the cerebral or cerebro-spinal symptoms are marked—tuberculous meningitis. Other forms have been recognized, but this division covers a large majority of the cases. Taking any series of cases it will be found that the meningeal form of acute tuberculosis exceeds in numbers the cases with general or marked pulmonary symptoms.

General or Typhoid Form.—SYMPTOMS.—The patient presents the symptoms of a profound infection which simulates and is frequently mistaken for typhoid fever. After a period of failing health, with loss of appetite, he becomes feverish and weak. Occasionally the disease sets in more abruptly, but in many instances the anamnesis closely resembles that of typhoid fever. Nose-bleeding, however, is rare. The temperature increases, the pulse becomes rapid and feeble, the tongue dry; delirium becomes marked and the cheeks are flushed. The pulmonary symptoms may be very slight; usually bronchitis exists, but is not more severe than is common with typhoid fever. The pulse is seldom dicrotic, but is rapid in proportion to the pyrexia. Perhaps the most striking feature of the temperature is the irregularity; and if seen from the outset there is not the steady ascent noted in typhoid fever. There is usually an evening rise to 103° F., sometimes 104° F., and a morning remission of from two to three degrees. Sometimes the pyrexia is intermittent, and the thermometer may register below normal during the early

morning hours. The inverse type of temperature, in which the rise takes place in the morning, is held by some writers to be more frequent in general tuberculosis than in other diseases. In rare instances there may be little or no fever. On four occasions we have had a patient admitted in a condition of profound debility, with a history of illness of from three to four weeks' duration, with rapid pulse, flushed cheeks, dry tongue, and very slight elevation in temperature, in whom (post mortem) the condition proved to be general tuberculosis. Reinhold, from Bäumer's clinic, called attention to these afebrile forms of acute tuberculosis. In 9 of 52 cases there was no fever, or only a transient rise.

In a considerable number of the cases the respirations are increased in frequency, particularly in the early stage, and there may be signs of diffuse bronchitis and slight cyanosis. Cheyne-Stokes breathing occurs toward the close. Active delirium is rare. More commonly there are torpor and dullness, gradually deepening into coma, in which the patient dies. In some cases the pulmonary symptoms become more marked; in others meningeal or cerebral features occur. The duration is usually from four to six weeks. Practically all the patients die.

DIAGNOSIS.—The differential diagnosis from typhoid fever may be difficult. A point of importance is the irregularity of the temperature curve. The greater frequency of the respirations and the tendency to slight cyanosis are much more common in tuberculosis. There are cases, however, of typhoid fever in which the initial bronchitis is severe and may lead to dyspnoea and cyanosis. The cough may be slight or absent. Diarrhoea is rare in tuberculosis; the bowels are usually constipated; but diarrhoea may occur and persist for days. In certain cases the diagnosis is complicated still further by the occurrence of blood in the stools. Enlargement of the spleen occurs in general tuberculosis, but is neither so early nor so marked as in typhoid fever. In children the enlargement may be considerable. The urine may show traces of albumin and contains tubercle bacilli in a considerable number of cases. The absence of the characteristic roseola is an important feature. Occasionally in acute tuberculosis reddish spots may occur and cause difficulty, but they do not come out in crops, and rarely have the characters of the true typhoid eruption. Herpes is perhaps more common in tuberculosis. Toward the close, petechiæ may appear on the skin, particularly about the wrists. A rare event is jaundice, due possibly to tubercles in the liver. The lesions of acute tuberculosis and of typhoid fever have been demonstrated in the same body.

A negative Widal test and blood-culture may be of decisive importance in these doubtful cases. In rare instances tubercle bacilli have been found in the blood. Leucocytosis is more common in miliary tuberculosis than in typhoid fever, in which leucopenia is the rule. Careful examination of the eyes may show choroidal tubercles, though we have never known a diagnosis made on their presence alone. In the fluid obtained by lumbar puncture the tubercle bacilli may be abundant, even when there is no active meningitis.

Pulmonary Form.—**SYMPTOMS.**—From the outset the pulmonary symptoms are marked. The patient may have had a cough for months or years without much impairment of health, or he may be known to have chronic

pulmonary tuberculosis. In other instances, particularly in children, the affection follows measles or whooping-cough, and is of a distinctly bronchopneumonic type. The disease begins with the symptoms of diffuse bronchitis. The cough is marked, the expectoration muco-purulent, occasionally rusty. Hæmoptysis has been noted in some instances. From the outset dyspnœa is a striking feature and may be out of proportion to the intensity of the physical signs. There is cyanosis and apart from emphysema and the later stages of severe pneumonia, there is no other pulmonary condition in which the cyanosis is so marked. The physical signs are those of bronchitis. In children there may be defective resonance at the bases, from scattered areas of broncho-pneumonia; or, what is equally suggestive, areas of hyper-resonance. Indeed, the percussion note, particularly in the front of the chest, in some cases of miliary tuberculosis, is full and clear, and it will be noted (post mortem) that the lungs are unusually voluminous. This is probably the result of more or less widespread acute emphysema. On auscultation, the râles are either sibilant and sonorous or small, fine, and crepitant. There may be fine crepitation from the occurrence of tubercles on the pleura (Jürgensen). In children there may be high-pitched tubular breathing at the bases or toward the root of the lung. Toward the close the râles may be larger and more mucous. The temperature rises to 102° or 103° F., and may present the inverse type. The pulse is rapid and feeble. In the very acute cases the spleen is always enlarged. The disease may prove fatal in ten or twelve days, or be protracted for weeks or even months. Chronic cases are described, in which the diagnosis is based largely on the X-ray findings, also used to estimate the progress.

DIAGNOSIS.—The diagnosis of this form offers less difficulty and is more frequently made. There is often a history of previous cough, or the patient is known to be the subject of tuberculosis. In children these symptoms following measles or whooping cough indicate in the majority of cases acute miliary tuberculosis, with or without broncho-pneumonia. Occasionally the sputum contains tubercle bacilli. The X-ray examination may be of great aid.

The choroidal tubercle occurs in a limited number of cases and may help the diagnosis. More important in an adult is the combination of dyspnœa with cyanosis and the signs of a diffuse bronchitis. In some instances the occurrence of cerebral symptoms gives a clew to the diagnosis.

Meningeal Form (*Tuberculous Meningitis*).—This affection, also known as acute hydrocephalus or “water on the brain,” is essentially an acute tuberculosis in which the membranes of the brain, sometimes of the cord, bear the brunt of the attack. Our first accurate knowledge of it dates from the publication of Robert Whytt’s Observations on the Dropsy of the Brain, Edinburgh, 1768. He studied 20 cases and divided the disease into three stages, according to the condition of the pulse.

Though Guersant had as early as 1827 used the name *granular meningitis* for this form of inflammation of the meninges, it was not until 1830 that Papavoine demonstrated the nature of the granules and noted their occurrence with tubercles in other parts. In 1832 and 1833, W. W. Gerhard, of Philadelphia, made a very careful study of the disease in the Children’s Hospital at Paris, and his publications, more than those of any other author, served to place the disease on a firm anatomical and clinical basis.

There are several special *etiological* factors in this form. It is much more common in children than in adults. It occurs during the first year of life, but is more frequent between the second and the fifth years. In a majority of the cases a focus of old tuberculous disease will be found, commonly in the bronchial or mesenteric glands. In a few instances the affection seems to be primary in the meninges. It is very difficult, however, in an ordinary post mortem to make an exhaustive search, and the lesion may be in the bones, sometimes in the middle ear, or in the genito-urinary organs. In cases in which no primary focus has been discovered it has been suggested that the bacilli reach the meninges through the cribriform plate of the ethmoid from the upper part of the nostrils, but this is not probable.

MORBID ANATOMY.—The meninges at the base are most involved, hence the term basilar meningitis. There may be only slight turbidity and matting of the membranes, and a certain stickiness with serous infiltration; but more commonly there is a turbid exudate, fibrino-purulent in character, which covers the structures at the base, surrounds the nerves, extends into the Sylvian fissures, and appears on the lateral, rarely on the upper, surfaces of the hemispheres. The tubercles may be very apparent, particularly in the Sylvian fissures, appearing as small, whitish nodules on the membranes. They vary much in number and size, and may be difficult to find. The amount of exudate bears no definite relation to the abundance of tubercles. The arteries of the anterior and posterior perforated spaces should be carefully withdrawn and searched, as upon them nodular tubercles may be found when not present elsewhere. In doubtful cases the middle cerebral arteries should be very carefully removed, spread on a glass plate with a black background, and examined with a lens. The tubercles are then seen as nodular enlargements on the smaller arteries. The lateral ventricles are dilated (acute hydrocephalus) and contain a turbid fluid; the ependyma may be softened, and the septum lucidum and fornix are usually broken down. The convolutions are often flattened and the sulci obliterated owing to the increased intra-ventricular pressure. The meninges are not alone involved, but the contiguous cerebral substance is more or less cedematous and infiltrated with leucocytes, so that the condition is in reality a *meningo-encephalitis*.

There are instances in which the acute process is associated with chronic meningeal tuberculosis, which may for months present the clinical picture of brain tumor. Although in a majority of instances the process is cerebral, the spinal meninges may also be involved, particularly those of the cervical cord. There are cases in which the symptoms are chiefly spinal.

SYMPTOMS.—Tuberculous meningitis presents an extremely complex clinical picture. It will be best to describe the form found in children.

Prodromal symptoms are common. The child may have been in failing health for some weeks, or may be convalescent from measles or whooping cough. In many instances there is a history of a fall. The child gets thin, is restless, peevish, irritable, loses its appetite, and the disposition may completely change. Suggestive symptoms may then set in, either suddenly with a convulsion, or more commonly with headache, vomiting, and fever, three essential symptoms of the onset which are rarely absent. The pain may be intense and agonizing. The child puts its hand to its head and occasionally, when the pain becomes worse, gives a short, sudden cry, the so-called

hydrocephalic cry. Sometimes the child screams continuously until utterly exhausted. The vomiting is without apparent cause and is independent of taking of food. Constipation is usually present. The fever is slight, but gradually rises to 102° to 103° F. The pulse is at first rapid, subsequently irregular and slow. The respirations are rarely altered. During sleep the child is restless and disturbed. There may be twitchings of the muscles, or sudden startings; or the child may wake up from sleep in great terror. In this early stage the pupils are usually contracted. These are the chief symptoms of the initial stage, or, as it is termed, the stage of irritation.

In the second period these irritative symptoms subside; vomiting is no longer marked, the abdomen becomes retracted, boat-shaped, or *carinated*. The bowels are obstinately constipated, the child no longer complains of headache, but is dull and apathetic, and when roused is more or less delirious. The head is often retracted and the child utters an occasional cry. The pupils are dilated or irregular, and a squint may develop. Sighing respiration is common. Convulsions may occur, or rigidity of the muscles of one side or of one limb. The temperature is variable, ranging from 100° to 102.5° F. A blotchy erythema is not uncommon. If the fingernail is drawn across the skin a red line comes out quickly, the so-called *tache cérébrale*, which has no diagnostic significance.

In the final period, or stage of *paralysis*, the coma increases and the child can not be roused. Convulsions are not infrequent, and there are spasmodic contractions of the muscles of the back and neck. Spasms may occur in the limbs of one side. Optic neuritis and paralysis of the ocular muscles may be present. The pupils become dilated, the eyelids are only partially closed, and the eyeballs are rolled up. Diarrhœa may occur, the pulse becomes rapid, and the child may sink into a toxic state with dry tongue, low delirium, and involuntary passages of urine and fæces. The temperature often becomes subnormal, sinking in rare instances to 93° or 94° F. In some cases there is an ante-mortem elevation, the fever rising to 106° F. The entire duration is from a fortnight to several weeks. A leucocytosis is not infrequently present throughout.

The clinical picture may be very varied, especially in adults and some cases pursue a rapid course. They set in with great violence, often in persons apparently in good health, and may prove fatal within a few days. In these instances, more common in adults, the convex surface of the brain is usually involved. There are again instances which are essentially chronic and display symptoms of a limited meningitis, sometimes with pronounced psychical symptoms, and sometimes with those of cerebral tumor. The symptoms may vary from time to time; some are probably due to toxæmia rather than to a local lesion.

There are certain features which call for special comment. The irregularity and slowness of the pulse in the early and middle stages of the disease are points upon which all authors agree. Toward the close, as the heart's action becomes weaker, the pulse is more frequent. The temperature is usually elevated but there are instances in which it does not rise in the whole course much above 100° F. It may be extremely irregular, and the oscillations are often as much as three or four degrees in the day. The ocular symptoms are of special importance. In the early stages nar-

rowing of the pupils is the rule. Toward the close, with increase in the intra-cranial pressure, the pupils dilate and are irregular. There may be conjugate deviation of the eyes. Of ocular nerves the third is most frequently involved, sometimes with paralysis of the face, limbs, and hypoglossal nerve on the opposite side (syndrome of Weber), due to a lesion limited to the inferior and internal part of the crus. In some cases when the head is flexed on the chest strabismus occurs in one or both eyes, lasting as long as the head is held flexed. The changes in the retinae are very important. *Neuritis* is the most common. According to Gowers, the disk at first becomes full colored and has hazy outlines, and the veins are dilated. Swelling and striation become pronounced, but the neuritis is rarely intense. Of 26 cases studied by Garlick, in 6 the condition was of diagnostic value. The tubercles in the choroid are much less frequently seen during life than post-mortem figures indicate.

Among the *motor* symptoms convulsions are most common, but there are other changes which deserve mention. A tetanic contraction of one limb may persist for several days, or a cataleptic condition. Tremor and athetoid movements are sometimes seen. The paralyzes are either hemiplegias or monoplegias. Hemiplegia may result from disturbance in the cortical branches of the middle cerebral artery, occasionally from softening in the internal capsule, due to involvement of the central branches. Of monoplegias, that of the face is perhaps most common, and if on the right side it may occur with aphasia. Brachial monoplegia may be associated with it. In the more chronic cases the symptoms persist for months, and there may be a characteristic Jacksonian epilepsy. Kernig's sign may be present, but is not constant. The Babinski reflex is sometimes found. The motor phenomena occur more often in adults and the usual signs of meningitis may be few. Unexplained constant severe headache may be the first symptom.

The DIAGNOSIS is rarely difficult. The sudden onset of persistent severe headache in tuberculous adults should excite suspicion, especially if there is any cranial nerve paralysis. Points upon which special stress is to be laid are the existence of a tuberculous focus in the body, the mode of onset and the symptoms, and the evidence obtained on lumbar puncture. The cerebro-spinal fluid is usually clear or slightly turbid, and after standing for 12 to 24 hours, a feathery clot of fibrin forms down the centre of the fluid. In this clot the tubercle bacilli are usually found. By centrifugalization, careful staining, and long search, tubercle bacilli can be found in a large proportion of cases—in 135 of 137 in one series (Hemenway). The cells are usually much increased in number; over 90 per cent. are small lymphocytes, though occasionally an excess of polymorphonuclear leucocytes is found.

The PROGNOSIS in this form is always most serious. We have seen neither a case proved to be tuberculous recover, nor post-mortem evidence of past disease of this nature. Rare cases of recovery have been reported by reliable authorities. Cramer and Bickel collected 46 undoubted cases in 1922.

TREATMENT.—In a disease which is practically always fatal this does not offer much. The patients should be nourished as well as possible and given sedatives to control restlessness or pain. In the meningeal form, lumbar puncture should be done frequently. There should be no hesitation in using sedatives freely when required.

III. TUBERCULOSIS OF THE LYMPHATIC SYSTEM

1. Tuberculosis of the Lymph-nodes (Scrofula)

Scrofula is tubercle, as it has been shown that the bacillus of Koch is the essential element. It is not definitely settled whether the organism which produces the chronic tuberculous adenitis differs from that which produces tuberculosis in other parts, or whether it is the local conditions in the glands which account for the slow development and milder course. The observations of Lingard are important as showing a variation in the virulence of the tubercle bacillus. Guinea-pigs inoculated with ordinary tubercle showed lymphatic infection within the first week and died within three months; infected with material from tuberculous glands, the lymphatic enlargement did not appear until the second or third week, and the animals survived for six or seven months. In 68 cases examined by A. S. Griffith, in 35 human and in 33 bovine infection was found. The proportion is higher in children under five, but of 17 cases twenty years old and upwards 4 were bovine. The cases of bovine infection in cervical gland tuberculosis in different countries analyzed by Griffith show that the proportion is lowest in Germany and highest in Scotland.

Tuberculous adenitis, met with at all ages, is more common in children than in adults, and may occur in old age. Tubercle bacilli are ubiquitous; all are exposed to infection, and upon the local conditions, whether favorable or unfavorable, depends the fate of those organisms which find lodgment in our bodies. A special predisposing factor in lymphatic tuberculosis is catarrh of the mucous membranes, which in itself excites slight adenitis of the neighboring glands. In a child with constantly recurring naso-pharyngeal catarrh, the bacilli which lodge on the mucous membranes find in all probability the gateways less strictly guarded and are taken up by the lymphatics and passed to the nearest glands. The importance of the *tonsils* as an infection-atrium has been urged. In conditions of health the local resistance is active enough to deal with the invaders, but the irritation of a chronic catarrh weakens the resistance of the lymph-tissue, and the bacilli are enabled to grow and gradually to change a simple into a tuberculous adenitis. The association of tubercle in the mesenteric glands with intestinal catarrh is thus explained. There has been a great decrease in tuberculous adenitis in the cities of the United States, probably due to pasteurization of milk.

The following are some of the features of interest in tuberculous adenitis:

(a) The local character. Thus, the glands of the neck, or at the bifurcation of the bronchi or those of the mesentery, may be alone involved. But there is usually a pulmonary lesion with involvement of the tracheo-bronchial nodes.

(b) The tendency to spontaneous healing. In a large proportion of the cases the battle which ensues between the bacilli and the protective forces is long; but the latter are finally successful, and we find in the calcified remnants in the bronchial and mesenteric lymph-glands evidences of victory. Too often in the bronchial glands a truce only is declared and hostilities may break out afresh in the form of an acute tuberculosis.

(c) The tendency of tuberculous adenitis to pass on to suppuration. The frequency with which, particularly in the glands of the neck, the tuberculous

process is associated with suppuration is a special feature. In nearly all instances the pus is sterile. Whether the suppuration is excited by the bacilli or by their products, or whether it is the result of a mixed infection with pus organisms, which are subsequently destroyed, is not settled.

(d) The existence of an unhealed tuberculous adenitis is a constant menace and in three-fourths of the instances of acute tuberculosis the infection is derived from this source. On the other hand, there is evidence that tuberculous adenitis in childhood gives immunity in adult life. Only a small number of adults with pulmonary tuberculosis show scars from adenitis—3.2 per cent. of one series of 2,000 patients. Certain autopsy studies suggest that in the bodies of adults with mesenteric gland tuberculosis, pulmonary tuberculosis is less frequent.

Generalized Tuberculous Lymphadenitis.—In exceptional instances we find diffuse tuberculosis of nearly all the lymph-glands of the body with little or no involvement of other parts. The most extreme cases of it, which we have seen, have been in negro patients. Two well-marked cases occurred at the Philadelphia Hospital. In a woman, the chart from April, 1888, until March, 1889, showed persistent fever, ranging from 101° to 103°, occasionally rising to 104° F. On December 16th the glands on the right side of the neck were removed. She died on March 5th. The lungs presented only one or two puckered spots at the apices. The bronchial, retro-peritoneal, and mesenteric glands were greatly enlarged and caseous. There was no intestinal, uterine, or bone disease. The continuous high fever depended apparently upon the tuberculous adenitis. In these instances the enlargement is most marked in the retro-peritoneal, bronchial, and mesenteric glands, but may be also present in the external glands. Occurring acutely, it presents a picture resembling Hodgkin's disease. In infants and children there is a form of general tuberculous adenitis in which the various groups of glands are successively, more rarely simultaneously, involved, and in which death is caused either by cachexia or by an acute miliary process.

Local Tuberculous Adenitis.—(a) CERVICAL.—This is the most common form in children, and is seen particularly among the poor and those who live among unsanitary conditions. Children in foundling hospitals and asylums are specially prone to the disease. In the United States it is most common in the negro race. It is often met with in catarrh of the nose and throat, or chronic enlargement of the tonsils; or the child may have had eczema of the scalp or a purulent otitis.

The submaxillary glands are first involved, and are popularly spoken of as enlarged kernels. They are usually larger on one side than on the other. As they increase in size, the individual tumors can be felt; the surface is smooth and the consistence firm. They may remain isolated, but more commonly they form large, knotted masses, over which the skin is, as a rule, freely movable. In many cases the skin ultimately becomes adherent, and inflammation and suppuration occur. An abscess points and, unless opened, bursts, leaving a sinus which heals slowly. The disease is frequently associated with coryza, with eczema of the scalp, ear, or lips, and with conjunctivitis or keratitis. When the glands are large and growing actively there is fever. The subjects are usually anæmic, particularly if suppuration has occurred. The progress of this form of adenitis is slow and tedious. Death.

however, rarely follows, and many aggravated cases in children do well. Not only the submaxillary group, but the glands above the clavicle and in the posterior cervical triangle, may be involved. In other instances the cervical and axillary glands are involved together, forming a continuous chain which extends beneath the clavicle and the pectoral muscle. With them the bronchial glands may also be enlarged and caseous. Not infrequently the enlargement of the supra-clavicular and axillary group of glands on the side precedes a tuberculous pleurisy or pulmonary tuberculosis.

(b) TRACHEO-BRONCHIAL.—The mediastinal lymph-glands constitute filters in which lodge the various foreign particles which escape the normal phagocytes of bronchi and lungs. Among these foreign particles, and probably attached to them, tubercle bacilli are not uncommon, and we find tubercles and caseous matter with great frequency in this group. Northrup found them involved in every one of 125 cases of tuberculosis at the New York Foundling Hospital. The tuberculous adenitis may, in the bronchial glands, attain the dimensions of a tumor of large size. In children the bronchial adenitis is apt to be associated with suppuration. The glands at the bifurcation of the trachea are first involved and chiefly on the right side—74 per cent. of Wollstein's cases. Irregular fever, failure of nutrition, loss of appetite, and lassitude may be caused by the absorption of toxins; pain is rare, though it is complained of sometimes in the mammary region. The cough is paroxysmal, often brassy, so that it has been mistaken for whooping cough. Stridor, when present, is more often expiratory. The physical signs are not very definite. Dilated veins over the anterior aspect of the thorax or in the axilla, absence of descent of the larynx during inspiration, and pain on pressure over the upper dorsal vertebrae are mentioned. Extension of the normal dulness over the upper four thoracic vertebrae to the fifth and sixth is of importance, and there may be para-vertebral dulness on delicate percussion. Some writers lay stress upon the whispered bronchophony over the upper thoracic vertebrae, and a venous hum may be heard sometimes over the manubrium. The X-ray pictures are usually distinctive.

Some of the more uncommon effects are: Compression of the superior cava, of the pulmonary artery, and of the azygos vein. The trachea and bronchi, though often flattened, are rarely seriously compressed. The vagus nerve may be involved, particularly the recurrent laryngeal branch. More important are the perforations of the softened glands into the bronchi or trachea, or a sort of secondary cyst may be formed between the lung and the trachea. Asphyxia has been caused by blocking of the larynx by a caseous gland which has ulcerated through the bronchus (Voelcker), and Cyril Ogle reported a case in which the ulcerated gland practically occluded both bronchi. Perforations of the vessels are much less common, but the pulmonary artery and the aorta have been opened. Perforation of the œsophagus has been described. One of the most serious effects is infection of the lung or pleura by the caseous glands situated deep along the bronchi. This may be by direct contact, and it may be difficult to determine in some sections where the caseous bronchial gland terminates and the pulmonary tissue begins. In other instances it takes place along the root of the lung and is subpleural. Among other sequences may be mentioned diverticulum of the œsophagus following adhesion of an enlarged gland and its subsequent retraction; and, in the case

of the anterior mediastinal and aortic groups, the frequent production of pericarditis, either by contact or by rupture of a softened gland into the sac. A serious danger is systemic infection, which takes place through the vessels.

(c) MESENTERIC; TABES MESENTERICA.—In this affection, the glands of the mesentery and retro-peritoneum become enlarged and caseate; more rarely they suppurate or calcify. A slight tuberculous adenitis is extremely common in children, and is often accidentally found (post mortem) when they have died of other diseases. It may be a primary lesion associated with intestinal catarrh, or secondary to tuberculous disease of the intestines.

The statistics of abdominal tuberculosis show a great variation in different localities. The small percentage in New York, less than one per cent. of all cases (Bovaird and Mt. Sinai Hospital figures), contrasts with the high figures given for Scotland by John Thomson, 3.5% for Edinburgh and 4.51 for Glasgow. "Scotland enjoys the unenviable distinction of having more abdominal tuberculosis than any other civilized country—twice as much at least as England generally, and more than ten times as much as Europe and North America." The involvement of the glands interferes seriously with nutrition, and the patients are puny, wasted, and anæmic. The abdomen is enlarged and tympanitic; diarrhœa is a constant feature; the stools are thin and offensive. There is moderate fever, but the general wasting and debility are the most characteristic features. The enlarged glands can not often be felt, owing to the distended condition of the bowels. These cases are often spoken of as "consumption of the bowels," but in a majority the intestines do not present tuberculous lesions. In a considerable number of the cases of tabes mesenterica the peritoneum is also involved, and in such the abdomen is large and hard, and nodules may be felt.

In adults tuberculous disease of the mesenteric glands may occur as a primary affection, or in association with pulmonary disease. It may exist without tuberculous disease in the intestines or in any other part. The tumor mass is usually a little to the right of the umbilicus, freely movable. The general symptoms are loss of weight and slight fever; locally there is pain, sometimes diarrhœa, and appendicitis is often suspected.

2. Tuberculosis of the Serous Membranes

General Serous Membrane Tuberculosis (*Polyorrrhomenitis*).—The serous membranes may be chiefly involved, simultaneously or consecutively, presenting a distinctive and readily recognizable clinical type of tuberculosis. There are three groups of cases. First, those in which an acute tuberculosis of the peritoneum and pleuræ occurs rapidly, caused by local disease of the tubes in women, or of the mediastinal or bronchial lymph-nodes. Secondly, cases in which the disease is more chronic, with exudation into both peritoneum and pleuræ, the formation of cheesy masses, and the occurrence of ulcerative and suppurative processes. Thirdly, there are cases in which the pleuro-peritoneal affection is still more chronic, the tubercles hard and fibroid, the membranes much thickened, and with little or no exudate. In any one of these three forms the pericardium may be involved with the pleuræ and peritoneum. It is important to bear in mind that there may be no visceral tuberculosis in these cases.

Tuberculosis of the Pleura.—(a) *Acute Tuberculous Pleurisy.*—It is difficult to estimate the proportion of instances of acute pleurisy due to tuberculosis (see *Acute Pleurisy*). The cases are rarely fatal. There are three groups of cases: (1) Acute tuberculous pleurisy with subsequent chronic course. (2) Secondary and terminal forms of acute pleurisy (these are not uncommon in hospital practice). And (3) a form of acute tuberculous suppurative pleurisy. A considerable number of the purulent pleurisies, designated as latent and chronic, are caused by tubercle bacilli, but the fact is not so widely recognized that there is an acute, ulcerative, and suppurative disease which may run a very rapid course. The pleurisy sets in abruptly, with pain in the side, fever, cough, and sometimes with a chill. There may be nothing to suggest a tuberculous process, and the subject may have a fine physique and come of healthy stock.

(b) *The subacute and chronic tuberculous pleurisies* are more common. The largest group comprises those with sero-fibrinous effusion. The onset is insidious, the true character of the disease is frequently overlooked, and in almost every instance there are tuberculous foci in the lungs and bronchial glands. These are cases in which the termination is often in pulmonary tuberculosis or general miliary tuberculosis. In a few cases the exudate becomes purulent.

(c) And, lastly, there is a chronic adhesive pleurisy, a primary proliferative form which is of long standing, and may lead to very great thickening of the membrane, and sometimes to invasion of the lung.

Secondary tuberculous pleurisy is very common. The visceral layer is usually involved in pulmonary tuberculosis. Adhesions form and a chronic pleurisy results, which may be simple, but usually tubercles are scattered through the adhesions. An acute tuberculous pleurisy may result from direct extension. The fluid may be sero-fibrinous or hæmorrhagic, or may become purulent. And, lastly, in pulmonary tuberculosis, a superficial spot of softening may perforate with the production of pyo-pneumothorax.

The general symptomatology of these forms will be considered under disease of the pleura.

Tuberculosis of the Pericardium.—Miliary tubercles may occur as a part of a general infection, but the term is properly limited to those cases in which, either as a primary or secondary process, there is extensive disease of the membrane. Tuberculosis is not so common in the pericardium as in the pleura and peritoneum, but it is certainly more common than the literature would lead us to suppose. George Norris found 82 instances among 1,780 post mortems in tuberculous subjects.

We may recognize four groups of cases: First, those in which the condition is entirely latent, and the disease is discovered accidentally in individuals who have died of other affections or of chronic pulmonary tuberculosis.

A second group, in which the symptoms are those of cardiac insufficiency following the dilatation and hypertrophy consequent upon a chronic adhesive pericarditis. The symptoms are those of cardiac dropsy, and suggest either idiopathic hypertrophy and dilatation, or, if there is a loud blowing systolic murmur at the apex, mitral valve disease. The condition of adherent pericardium is usually overlooked.

In a third group the clinical picture is that of an acute tuberculosis, either

general or with cerebro-spinal manifestations, which has had its origin from the tuberculous pericardium or tuberculous mediastinal lymph-glands.

A fourth group, with symptoms of acute pericarditis, includes cases in which the affection is acute and accompanied with more or less exudation of a sero-fibrinous, hæmorrhagic, or purulent character. There may be no suspicion whatever of the tuberculous nature of the trouble.

Tuberculosis of the Peritoneum.—In connection with miliary and chronic pulmonary tuberculosis it is not uncommon to find the peritoneum studded with small gray granulations. They are constantly present on the serous surface of tuberculous ulcers of the intestines. Apart from these conditions the membrane is often the seat of extensive tuberculous disease, which occurs in the following forms:

(a) *Acute miliary tuberculosis* with sero-fibrinous or bloody exudation.

(b) *Chronic tuberculosis*, characterized by larger growths, which tend to caseate and ulcerate. The exudate is purulent or sero-purulent, and is often sacculated.

(c) *Chronic fibroid tuberculosis*, which may be subacute from the onset, or which may represent the final stage of an acute miliary eruption. The tubercles are hard and pigmented. There is little or no exudation, and the serous surfaces are matted together by adhesions.

The process may be primary and local, which was the case in 5 of 17 post mortems. In children the infection appears to pass from the intestines, and in adults this is the source in the cases associated with chronic tuberculosis. In women the disease extends commonly from the fallopian tubes. In at least 30 or 40 per cent. of the instances of laparotomy in this affection the infection was from them. The prostate or the seminal vesicles may be the starting-point. In many cases the peritoneum is involved with the pleura and pericardium, particularly with the former membrane.

Certain morbid conditions of the abdominal organs predispose to the development of the disease; thus patients with cirrhosis of the liver often die of an acute tuberculous peritonitis. The frequency with which the condition is met with in operations upon ovarian tumors has been commented upon by gynæcologists. Many cases have followed trauma of the abdomen. An interesting feature is the not uncommon occurrence of tuberculosis in hernial sacs. In a majority of the instances it is discovered accidentally during the operation for radical cure or for strangulation. In some instances the sac alone is involved.

It is generally stated that males are attacked oftener than females, but in the collected statistics the cases are twice as numerous in females as in males; in the ratio, indeed, of 131 to 60.

Tuberculous peritonitis occurs at all ages, but is most frequent between the ages of 20 and 40. It may occur in advanced life; one patient was 82 years of age. It is common in children associated with intestinal and mesenteric disease. Of 357 cases from the literature, there were under ten years, 27; between ten and twenty, 75; from twenty to thirty, 87; between thirty and forty, 71; from forty to fifty, 61; from fifty to sixty, 19; from sixty to seventy, 4; above seventy, 2. In America it is more common in the negro than in the white race. More blacks than whites, 77 to 70, were admitted to the Johns Hopkins Hospital (Hamman).

SYMPTOMS.—In certain special features the tuberculous varies considerably from other forms of peritonitis. It presents a symptom-complex of extraordinary diversity.

In the first place, the process may be latent and met with accidentally in the operation for hernia or for ovarian tumor. An acute onset is not uncommon. Four cases in our records were diagnosed appendicitis, two acute cholecystitis, and six had symptoms of intestinal obstruction, in two of these coming on with great abruptness (Hamman). The cases have been mistaken for strangulated hernia. Other cases set in acutely with fever, abdominal tenderness, and the symptoms of ordinary acute peritonitis. Cases with a slow onset, abdominal tenderness, tympanites, and low continuous fever may be mistaken for typhoid fever.

Ascites is frequent, but the effusion is rarely large. It is sometimes hæmorrhagic. In this form the diagnosis may rest between an acute miliary cancer, cirrhosis of the liver, and a chronic simple peritonitis—conditions which usually offer no special difficulties in differentiation. A most important point is the simultaneous presence of a pleurisy. The tuberculin test may be used. Tympanites may be present in the very acute cases, when it is due to loss of tone in the intestines owing to inflammatory infiltration; or it may occur in the old, long-standing cases when universal adhesion has taken place between the parietal and visceral layers. Fever is a marked symptom in the acute cases, and the temperature may reach 103° or 104° F. In many instances the fever is slight. In the more chronic cases subnormal temperatures are common, and for days the temperature may not rise above 97°, and the morning record may be as low as 95.5°. An occasional symptom is pigmentation of the skin, which has led to the diagnosis of Addison's disease. A striking peculiarity of tuberculous peritonitis is the frequency with which it simulates or is associated with tumor. This may be:

(a) Omental, due to puckering and rolling of this membrane until it forms an elongated firm mass, attached to the transverse colon and lying athwart the upper part of the abdomen. This cord-like structure is found also with cancerous peritonitis, but is much more common in tuberculosis. Gairdner called special attention to this form of tumor, and in children saw it undergo gradual resolution. A resonant percussion note may sometimes be elicited above the mass. Though usually situated near the umbilicus, the omental mass may form a prominent tumor in the right iliac region.

(b) Sacculated exudation, in which the effusion is limited and confined by adhesions between the coils, the parietal peritoneum, the mesentery, and the abdominal or pelvic organs. This encysted exudate is most common in the middle zone, and has frequently been mistaken for ovarian tumor. It may occupy the entire anterior portion of the peritoneum, or there may be a more limited saccular exudate on one side or the other. Within the pelvis it is associated with disease of the fallopian tubes. Eighteen cases in the gynæcological wards (J. H. H.) were operated upon for pyosalpinx (Hamman).

(c) In rare cases the tumor formations may be due to great retraction or thickening of the intestinal coils. The small intestine is found shortened, the walls enormously thickened, and the entire coil may form a firm knot close against the spine, giving on examination the idea of a solid mass. Not

the small intestine only, but the entire bowel from the duodenum to the rectum, has been found forming such a hard nodular tumor.

(d) Mesenteric glands occasionally form very large, tumor-like masses, more commonly found in children than in adults. This condition may be confined to the abdominal glands. Ascites may coexist. The condition must be distinguished from that in children, in which, with ascites or tympanites—sometimes both—there can be felt irregular nodular masses, due to large caseous formations between the intestinal coils. No doubt in a considerable number of cases of the so-called *tabes mesenterica*, particularly in those with enlargement and hardness of the abdomen—the condition which the French call *carreau*—there is involvement also of the peritoneum.

The *diagnosis* of these peritoneal tumors is sometimes very difficult. The omental mass is a less frequent source of error than any other; but a similar condition may occur in cancer. The most important problem is the diagnosis of the saccular exudation from ovarian tumor. In fully one-third of the recorded cases of laparotomy in tuberculous peritonitis the diagnosis of ovarian disease has been made. The most suggestive points for consideration are the history and the evidence of old tuberculous lesions. The physical condition is not of much help, as in many instances the patients are robust and well nourished. Irregular febrile attacks, gastro-intestinal disturbance, and pains are more common in tuberculous disease. Unless inflamed there is usually not much fever with ovarian cysts. The local signs are very deceptive, and may conform in every particular to those of cystic disease. The outlines in saccular exudation are rarely so well defined. The position and form may be variable, owing to alterations in the size of the coils of which in parts the walls are composed. Nodular cheesy masses may sometimes be felt at the periphery. Depression of the vaginal wall is mentioned as occurring in encysted peritonitis; but it is also found in ovarian tumor. The condition of the fallopian tubes, of the lungs and the pleuræ, should be thoroughly examined. The association of salpingitis with an ill-defined anomalous mass in the abdomen should arouse suspicion, as should also involvement of the pleura, the lung, or an epididymis or seminal vesicle in the male.

TREATMENT.—General measures should be carried out as in pulmonary tuberculosis. Direct exposure of the abdomen to heliotherapy and to the X-rays has proved useful in some cases. Surgical treatment is most helpful in cases with ascites, but when there are tuberculous tumors and many adhesions the results are not satisfactory. In some cases the removal of a focus of infection, such as tuberculous mesenteric glands, a diseased appendix or a tuberculous fallopian tube, has been of benefit.

IV. PULMONARY TUBERCULOSIS

(*Phthisis, Consumption*)

Three clinical groups may be recognized: (1) acute pneumonic tuberculosis; (2) chronic ulcerative tuberculosis; and (3) fibroid tuberculosis.

According to the mode of infection there are two distinct types of lesions:

(a) When the bacilli reach the lungs through the blood-vessels or lymphatics the primary lesion is usually in the tissues of the alveolar walls, in

the capillary vessels, the epithelium of the air-cells, and in the connective-tissue framework of the septa. The irritation of the bacilli produces the small, gray, miliary nodules, involving several alveoli and consisting largely of round, cuboidal, uninuclear epithelioid cells. Depending upon the number of bacilli which reach the lung in this way, either a localized or a general tuberculosis is excited. The tubercles may be scattered through both lungs and form part of a general miliary tuberculosis, or be confined to the lungs, or even in great part to one lung. The further stages may be: (1) Arrest of the process of cell division, gradual sclerosis of the tubercle, and ultimately complete fibroid transformation. (2) Caseation of the centre of the tubercle, extension at the periphery by proliferation of the epithelioid and lymphoid cells, so that the individual tubercles or small groups become confluent and form diffuse areas which undergo caseation and softening. (3) Occasionally as a result of intense infection of a localized region through the blood-vessels the tubercles are thickly set. The intervening tissue becomes acutely inflamed, the air-cells are filled with the products of a desquamative pneumonia, and many lobules are involved.

(b) When the bacilli reach the lung through the bronchi—inhalation or aspiration tuberculosis—the picture differs. The smaller bronchi and bronchioles are more extensively affected; the process is not confined to single groups of alveoli, but has a more lobular arrangement, and the tuberculous masses from the onset are larger, more diffuse, and may in some cases involve an entire lobe or the greater part of a lung. It is in this mode of infection that we see the characteristic peri-bronchial granulations and the areas of the so-called nodular broncho-pneumonia. These broncho-pneumonic areas, with on the one hand caseation, ulceration, and cavity formation, and on the other sclerosis and limitation, make up the essential elements in the anatomical picture of pulmonary tuberculosis.

1. *Acute Pneumonic Tuberculosis*

This form, known also as *galloping consumption*, occurs both in children and adults. Many of the cases are mistaken for simple broncho-pneumonia.

Two types may be recognized, the *pneumonic* and *broncho-pneumonic*.

Pneumonic Form.—In this one lobe may be involved, or in some instances an entire lung. The organ is heavy, the affected portion airless; the pleura is usually covered with a thin exudate, and on section the picture resembles closely that of ordinary hepatization. The following is an extract from the post-mortem report of a case in which death occurred twenty-nine days after the onset of the illness, having all the characters of an acute pneumonia: "Left lung weighs 1,500 grams (double the weight of the other organ) and is heavy and airless, crepitant only at the anterior margins. Section shows a small cavity the size of a walnut at the apex, about which are scattered tubercles in a consolidated tissue. The greater part of the lung presents a grayish-white appearance due to the aggregation of tubercles which in some places have a continuous, uniform appearance, in others are surrounded by injected and consolidated lung-tissue. Toward the margins of the lower lobe strands of this firm reddish tissue separate anæmic, dry areas. There are in the right lung four small groups of tubercles but no caseous

masses. The bronchial glands are not tuberculous." Here the intense local infection was due to the small focus at the apex of the lung, probably an aspiration process.

Only the most careful inspection may reveal the presence of miliary tubercles, or the attention may be arrested by the detection of tubercles in the other lung or in the bronchial glands. The process may involve only one lobe. There may be older areas which are of a yellowish-white color and distinctly caseous. The most remarkable picture is presented by cases of this kind in which the disease lasts for some months. A lobe or an entire lung may be enlarged, firm, airless throughout, and converted into a dry, yellowish-white, cheesy substance. In some cases the entire lung is in this condition, with perhaps only a narrow area of air-containing tissue on the margin. More commonly, if the disease has lasted for two or three months, rapid softening has taken place at the apex with extensive cavity formation.

Males are much more frequently attacked than females. Of a series of 15 cases, 11 were males. The onset was acute in 13, with a chill in 9. Bacilli were found in the sputum in one case as early as the fourth day. Fraenkel and Troje believe that the cases are of bronchogenous origin, due to infection from a small focus somewhere in the lung. Tendeloo regards the infection as sometimes hæmatogenous.

SYMPTOMS.—The attack sets in abruptly with a chill, usually in an individual who has enjoyed good health, although in many cases the onset has been preceded by exposure to cold, or there have been debilitating circumstances. The temperature rises rapidly after the chill, there is pain in the side and cough, with at first mucoid, subsequently rusty-colored expectoration which may contain tubercle bacilli. The dyspnoea may become extreme and the patient may have suffocative attacks. The physical examination shows involvement of one lobe or of one lung, with signs of consolidation, dullness, increased fremitus, at first feeble or suppressed vesicular murmur, and subsequently well-marked bronchial breathing.

At this time, as a rule, no suspicion enters the mind of the practitioner that the case is anything but one of frank lobar pneumonia. Occasionally there may be suspicious circumstances in the history but, as a rule, no stress is laid upon them in view of the characteristic mode of onset. Between the eighth and tenth day, instead of the expected crisis, the condition becomes aggravated, the temperature is irregular, and the pulse more rapid. There may be sweating, and the expectoration becomes muco-purulent and greenish in color—a point of special importance, to which Traube called attention. Even in the second or third week, with the persistence of these symptoms, the physician tries to console himself with the idea that the case is one of unresolved pneumonia, and that all will yet be well. Gradually, the severity of the symptoms, the presence of physical signs indicating softening, the existence of elastic tissue and tubercle bacilli in the sputum present the mournful proofs that the case is one of acute pneumonic tuberculosis. Death may occur on the sixth day, as in a case of Tendeloo's. The earliest death in our series was on the thirteenth day. A majority of the cases drag on, and death does not occur until the third month. In a few cases, even after a stormy onset and active course, the symptoms subside and the patient passes into the chronic stage.

DIAGNOSIS.—Waters, of Liverpool, who gave an admirable description of these cases, called attention to the difficulty in distinguishing them from ordinary pneumonia. Certainly the mode of onset affords no criterion whatever. A healthy young Irishman, a cab-driver, who had been kept waiting on a cold, blustering night until three in the morning, was seized the next afternoon with a violent chill, and the following day was admitted to the University Hospital, Philadelphia. He was made the subject of a clinical lecture on the fifth day, when there was absent no single feature in history, symptoms, or physical signs of acute lobar pneumonia of the right upper lobe. It was not until ten days later, when bacilli were found in the sputum, that we were made aware of the true nature of the case. There is no criterion by which cases of this kind can be distinguished in the early stage. A point to which Traube called attention, and referred to as important by Hérard and Cornil, is the absence of breath-sounds in the consolidated region; but this does not hold good in all cases. The tubular breathing may be intense and marked as early as the fourth day; and how common it is to have, as one of the earliest and most suggestive of signs of lobar pneumonia, suppression or enfeeblement of the breath-sounds. In many cases, however, there are suspicious circumstances in the onset: the patient has been in bad health, or may have had previous pulmonary trouble, or there are recurring chills. Careful examination of the sputum and a study of the physical signs from day to day can alone determine the true nature of the case. A point of some moment is the character of the fever, which in true pneumonia is more continuous, particularly in severe cases, whereas in this form of tuberculosis remissions are not infrequent. When ordinary lobar pneumonia occurs in a patient with chronic pulmonary tuberculosis, time alone can determine whether it is pneumococcal or tuberculous.

Acute Tuberculous Broncho-pneumonia.—This is more common, particularly in children, and forms a majority of the cases of *phthisis florida*, or “galloping consumption.” It is an acute caseous broncho-pneumonia, starting in the smaller tubes, which become blocked with a cheesy substance, while the air cells of the lobule are filled with the products of a catarrhal pneumonia. In the early stages the areas have a grayish red, later an opaque white, caseous appearance. By the fusion of contiguous masses an entire lobe may be rendered nearly solid, but areas of crepitant air tissue can usually be seen between the groups. This is not uncommon in the acute tuberculosis of adults but is still more frequent in children. The following is from the post-mortem report of a case on a child aged four months, who died in the sixth week of illness: “On section, the right upper lobe is occupied with caseous masses from 5 to 12 mm. in diameter, separated from each other by an intervening tissue of a deep red color. The bronchi are filled with cheesy substance. The middle and lower lobes are studded with tubercles, many of which are becoming caseous. Toward the diaphragmatic surface of the lower lobe there is a small cavity the size of a marble. The left lung is more crepitant and uniformly studded with tubercles of all sizes, some as large as peas. The bronchial glands are very large, and one contains a tuberculous abscess.”

There is a form of tuberculous *aspiration* pneumonia, to which Bäumler called attention, occurring as a sequence of hæmoptysis, and due to the aspiration of blood and the contents of pulmonary cavities into the finer tubes.

There are fever, dyspnoea, and signs of a diffuse broncho-pneumonia. Some of these cases run a very rapid course. This accident may occur early in the disease or follow hæmorrhage in a well-marked pulmonary tuberculosis.

In children the enlarged bronchial glands usually surround the root of the lung, and even pass deeply into the substance, and the lobules are often involved by direct contact.

In other cases the caseous broncho-pneumonia involves groups of alveoli or lobules in different portions of the lungs, more commonly at both apices, forming areas from 1 to 3 cm. in diameter. The size of the mass depends largely upon that of the bronchus involved. There are cases which probably come in this category, in which, with an acute illness of from four to eight weeks, the lungs are extensively studded with large gray tubercles, ranging in size from 5 to 10 mm. In some instances there are cheesy masses the size of a cherry. All of these are grayish-white, distinctly cheesy, and between the adjacent ones, particularly in the lower lobe, there may be recent pneumonia, or the condition termed splenization. In a case of this kind at the Philadelphia Hospital death took place about the eighth week from the abrupt onset of the illness with hæmorrhage. There were no extensive areas of consolidation, but the cheesy nodules were uniformly scattered throughout both lungs. No softening had taken place.

Secondary infections are not uncommon; but Prudden was able to show that the tubercle bacillus could produce not only distinct tubercle nodules, but also the various kind of exudative pneumonia, the exudates varying in appearance in different cases, which phenomena occurred absolutely without other organisms. These exudative phenomena represent the influence of re-infection in tissues sensitized by previous infection.

SYMPTOMS.—The symptoms of acute broncho-pneumonic tuberculosis are very variable. In adults the disease may attack persons in good health, but over-worked or “run down.” Hæmorrhage initiates the attack in a few cases. There may be repeated chills; the temperature is high, the pulse rapid, and the respirations increased. The loss of flesh and strength is striking.

The physical signs may at first be uncertain and indefinite, but finally there are areas of impaired resonance, usually at the apices; the breath-sounds are harsh and tubular, with numerous râles. The sputum may early show elastic tissue and tubercle bacilli. In the acute cases, within three weeks, the patient may be in a marked toxic state, with delirium, dry tongue, and high fever. Death may occur within three weeks. In other cases the onset is severe, with high fever, rapid loss of flesh and strength, and signs of extensive unilateral or bilateral disease. Softening takes place and there are sweats, chills, and progressive emaciation. Six or eight weeks later the patient may begin to improve, the fever lessens, the general symptoms abate, and a case which looked as if it would terminate fatally within a few weeks drags on and becomes chronic.

In children the disease most commonly follows the infectious diseases, particularly measles and whooping cough. At least three groups of these tuberculous broncho-pneumonias may be recognized. In the first the child is taken ill suddenly while teething or during convalescence from fever; the temperature rises rapidly, the cough is severe, and there may be signs of consolidation at one or both apices with râles. Death may occur within a few

days, and the lung shows areas of broncho-pneumonia, with perhaps here and there scattered opaque grayish-yellow nodules. Macroscopically the affection does not look tuberculous, but histologically miliary granulations and bacilli may be found. Tubercles are usually present in the bronchial glands, but the appearance of the broncho-pneumonia may be exceedingly deceptive, and it may require careful microscopic examination to determine its tuberculous character. The *second group* is represented by the case of the child previously quoted, who died in the sixth week with the ordinary symptoms of severe broncho-pneumonia. And the *third group* is that in which, during the convalescence from an infectious disease, the child is taken ill with fever, cough, and shortness of breath. The severity of the symptoms abates within the first fortnight; but there is loss of flesh, the general condition is bad, and the physical examination shows the presence of scattered râles throughout the lungs, and here and there areas of defective resonance. The child has sweats, the fever becomes hectic in character, and in many cases the clinical picture gradually passes into that of chronic pulmonary tuberculosis.

2. Chronic Ulcerative Tuberculosis of the Lungs

Under this heading may be grouped the great majority of cases of pulmonary tuberculosis, in which the lesions proceed to ulceration and softening.

Morbid Anatomy.—Inspection of the lungs shows a remarkable variety of lesions, comprising nodular tubercles, diffuse tuberculous infiltration, caseous masses, pneumonic areas, cavities of various sizes, with changes in the pleura, bronchi, and bronchial glands.

DISTRIBUTION OF THE LESIONS.—For years it has been recognized that the most advanced lesions are at the apices, and that the disease progresses downward, usually more rapidly in one of the lungs. This general statement, accepted ever since the masterly description of Laennec, has been carefully elaborated by Kingston Fowler, who finds that the disease in its onward progress through the lungs follows, in a majority of the cases, distinct routes. In the upper lobe the primary lesion is not, as a rule, at the extreme apex, but from an inch to an inch and a half below it, and nearer to the posterior and external borders. The lesion here tends to spread downward, probably from inhalation of the virus, and this accounts for the frequent circumstance that examination behind, in the supra-spinous fossa, may give indications of disease before any evidences exist at the apex in front. Anteriorly this initial focus corresponds to a spot just below the centre of the clavicle, and the direction of extension in front is along the anterior aspect of the upper lobe, along a line running about an inch and a half from the inner ends of the first, second, and third interspaces. A second less common site of the primary lesion in the apex "corresponds on the chest wall with the first and second interspaces below the outer third of the clavicle." The extension is downward, so that the outer part of the upper lobe is chiefly involved.

In the middle lobe of the right lung the affection usually follows disease of the upper lobe on the same side. In the involvement of the lower lobe the first secondary infiltration is about an inch to an inch and a half below the posterior extremity of its apex, and corresponds on the chest wall to a spot opposite the fifth dorsal spine. This involvement is of the greatest im-

portance clinically, as "in the great majority of cases, when the physical signs of the disease at the apex are sufficiently definite to allow of the diagnosis of phthisis being made, the lower lobe is already affected." Examination, therefore, should be made carefully of this posterior apex in all suspicious cases. In this situation the lesion spreads downward and laterally along the line of the interlobular septa, a line which is marked by the vertebral border of the scapula, when the hand is placed on the opposite scapula and the elbow raised above the level of the shoulder. Once present in an apex, the disease usually extends in time to the opposite upper lobe; but not, as a rule, until the apex at the lower lobe of the lung first affected has been attacked. Of 427 cases, the right apex was involved in 172, the left in 130, both in 111.

Lesions of the base may be primary, though this is rare. Percy Kidd makes the proportion of basal to apical tuberculosis 1 to 500. In very chronic cases there may be arrested lesions at the apex and more recent lesions at the base.

SUMMARY OF THE LESIONS IN CHRONIC ULCERATIVE TUBERCULOSIS.—(a) *Miliary Tubercles.*—They have one of two distributions: (1) A dissemination due to aspiration of tuberculous material, the tubercles being situated in the air-cells or the walls of the smaller bronchi; (2) the distribution due to dissemination of tubercle bacilli by the lymph current, the tubercles being scattered about the old foci in a radial manner—the secondary crop of Laennec. Much more rarely there is a scattered dissemination from infection here and there of the smaller vessels, the tubercles being situated in the vessel walls. Sometimes, with cavity formation at the apex, the greater part of the lower lobes presents many groups of sclerotic, miliary tubercles, which may form the distinguishing anatomical feature—a chronic miliary tuberculosis.

(b) *Tuberculous Broncho-pneumonia.*—In a large proportion of cases of chronic tuberculosis the terminal bronchiole is the point of origin of the process, consequently we find the smaller bronchi and their alveolar territories blocked with the accumulated products of inflammation in all stages of *caseation*. At an early period a cross-section of an area of tuberculous broncho-pneumonia gives the most characteristic appearance. The central bronchiole is seen as a small orifice, or it is plugged with cheesy contents, while surrounding it is a caseous nodule, the so-called peribronchial tubercle. The longitudinal section has a somewhat dendritic or foliaceous appearance. The condition of the picture depends much upon the slowness or rapidity with which the process has advanced. The following changes may occur:

Ulceration.—When the caseation takes place rapidly or ulceration occurs in the bronchial wall, the mass may break down and form a small cavity.

Sclerosis.—In other instances the process is more chronic, and fibroid changes gradually produce a sclerosis of the affected area. This may be confined to the margin of the mass, forming a limiting capsule, within which is a uniform, firm, cheesy substance, in which lime salts are often deposited. This represents the healing of one of these areas of caseous broncho-pneumonia. It is only, however, when complete fibroid transformation or calcification has occurred that we can really speak of healing. In many instances the colonies of miliary tubercles about these masses show that the process is still active. Subsequently, in ulcerative processes, these calcareous bodies—lung-stones, as they are sometimes called—may be expectorated.

(c) *Pneumonia*.—An important though secondary place is occupied by inflammation of the alveoli surrounding the tubercles, which become filled with epithelioid cells. The consolidation may extend for some distance about the tuberculous foci and unite them into areas of uniform consolidation. Although in some instances this inflammatory process may be simple, in others it is undoubtedly specific and is excited by the tubercle bacilli. It may present a very varied appearance; in some instances resembling ordinary red hepatization, in others being more homogeneous and infiltrated. In other cases the contents of the alveoli undergo fatty degeneration, and appear on the cut surface as opaque white or yellowish-white bodies. In early tuberculosis much of the consolidation is due to this pneumonic infiltration, which may surround the smaller foci for some distance.

(d) *Cavities*.—A vomica is a cavity in the lung tissue, produced by necrosis and ulceration. The process usually begins in the wall of the bronchus in a tuberculous area. Dilatation is produced by retained secretion, and necrosis and ulceration of the wall occur with gradual destruction of the contiguous tissues. By extension of the necrosis and ulceration the cavity increases, contiguous ones unite, and in an affected region there may be a series of small excavations communicating with a bronchus. In nearly all instances the process extends from the bronchi, though it is possible for necrosis and softening to take place in the centre of a caseous area without primary involvement of the bronchial wall. Three forms may be recognized.

The *fresh ulcerative*, seen in acute cases, in which there is no limiting membrane, but the walls are made up of softened, necrotic, and caseous masses. A small vomica of this sort, situated just beneath the pleura, may rupture and cause pneumothorax. In cases of acute pneumonic tuberculosis they may be large, occupying the greater portion of the upper lobe. In the chronic ulcerative form, cavities of this sort are invariably present in those portions of the lung in which the disease is advancing. At the apex there may be a large old cavity with well-defined walls, while at the interior margin of the upper lobes, or in the apices of the lower lobes, there are recent ulcerating cavities communicating with the bronchi.

Cavities with Well-defined Walls.—A majority of the cavities in the chronic cases have a well-defined limiting membrane, the inner surface of which constantly produces pus. The walls are crossed by trabeculae which represent remnants of bronchi and blood-vessels. Even the cavities with the well-defined walls extend gradually by a slow necrosis and destruction of the contiguous lung tissue. The contents are usually purulent, similar in character to the grayish nummular sputa coughed up. Not infrequently the membrane is vascular or it may be hæmorrhagic. Occasionally, when gangrene has occurred, the contents are horribly fetid. These cavities may occupy the greater portion of the apex, forming an irregular series which communicate with each other and with the bronchi, or the entire upper lobe except the anterior margin may be excavated, forming a thin-walled cavity. In rare instances the process has proceeded to total excavation of the lung, not a remnant of which remains, except perhaps a narrow strip at the anterior margin. In a case of this kind, the cavity held 40 fluid ounces, in another 42 ounces.

Quiescent Cavities.—When quite small and surrounded by dense cicatricial tissue communicating with the bronchi they form the *cicatrices fistuleuses* of

Laennec. Occasionally one apex may be represented by a series of these small cavities, surrounded by dense fibrous tissue. The lining membrane of these old cavities may be quite smooth, almost like a mucous membrane. Cavities of any size do not heal completely. Cases are often seen in which it has been supposed that a cavity has healed; but the signs of excavation are notoriously uncertain, and there may be pectoriloquy and cavernous sounds with gurgling resonant râles in an area of consolidation close to a large bronchus.

In the formation of cavities the blood-vessels gradually become closed by an obliterating inflammation. They are the last structures to yield and may be completely exposed in a cavity, even when the circulation is still going on in them. The erosion of a large vessel which has not been obliterated is by no means infrequent, and causes profuse hæmorrhage. Another common event is the formation of aneurisms on the arteries running in the walls of cavities. These may be small dilatations, or may form sacs the size of a walnut or even larger. They are important with regard to hæmoptysis.

And, finally, about cavities of all sorts, the connective tissue grows, tending to limit their extent. The thickening is particularly marked beneath the pleura, and in chronic cases an entire apex may be converted into a mass of fibrous tissue, inclosing a few small cavities.

(e) *Pleura*.—Practically, in all cases of chronic tuberculosis the pleura is involved. Adhesions take place which may be thin and readily torn, or dense and firm, uniting layers of from 2 to 5 mm. in thickness. This pleurisy may be simple, but in many cases it is tuberculous, and miliary tubercles or caseous masses are seen in the thickened membrane. Effusion is not infrequent: serous, purulent, or hæmorrhagic. Pneumothorax is a common accident.

(f) Changes in the smaller bronchi control the situation in the early stages of pulmonary tuberculosis, and play an important rôle throughout. The process very often begins in the walls of the smaller tubes and leads to caseation, distention with products of inflammation, and broncho-pneumonia of the lobules. In many cases the visible implication of the bronchus is an extension upward of a process which has begun in the smallest bronchiole. This involvement weakens the wall, leading to bronchiectasis, not an uncommon event. The mucous membrane of the larger bronchi, which is usually involved in a chronic catarrh, is more or less swollen, and in some instances ulcerated. Besides these specific lesions, they may be the seat, especially in children, of inflammation due to secondary invasion, most frequently by the pneumococcus with the production of a broncho-pneumonia.

(g) The bronchial glands, in the more acute cases, are swollen and oedematous. Miliary tubercles and caseous foci are usually present. In cases of chronic tuberculosis the caseous areas are common, calcification may occur, and not infrequently purulent softening.

(h) *Changes in the Other Organs*.—Of these, tuberculosis is the most common. In 275 autopsies the brain presented tuberculous lesions in 31, the spleen in 33, the liver in 12, the kidneys in 32, the intestines in 65, and the pericardium in 7. Other groups of lymphatic glands besides the bronchial may be affected.

Amyloid change may occur in the liver, spleen, kidneys, and mucous membrane of the intestines. The liver is often the seat of extensive fatty infiltration.

tion, which may cause marked enlargement. The *intestinal tuberculosis* occurs in advanced cases and is responsible in great part for the diarrhoea.

Endocarditis is not very common, and was present in 12 of 275 post mortems and in 27 of Percy Kidd's 500 cases. Tubercle bacilli have been found in the vegetations. Tubercles may be present on the endocardium, particularly of the right ventricle.

The *larynx* is frequently involved, and ulceration of the vocal cords and destruction of the epiglottis are not at all uncommon.

Modes of Onset.—We have already seen that tuberculosis of the lungs may occur as the chief part of a general infection, or may set in with symptoms which closely simulate acute pneumonia. In the ordinary type of pulmonary tuberculosis the invasion is gradual and less striking, but presents an extraordinarily diverse picture, so that the practitioner is often led into error. Among the most characteristic modes of onset are the following:

(a) **LATENT TYPES.**—Many such cases are found in the routine examination of large groups of people. It is probable that many slight, ill-defined ailments are due to unrecognized tuberculosis. In the history of patients with tuberculosis such attacks are not infrequently mentioned. The disease may make considerable progress before serious symptoms arouse the attention of the patient. In workingmen the disease may even advance to excavation of an apex before they seek advice. It is not a little remarkable how slight the lung symptoms may have been. The symptoms may be masked by the existence of serious disease in other organs, as in the peritoneum, intestines, or bones.

(b) **WITH SYMPTOMS OF DYSPEPSIA AND ANÆMIA.**—The gastric mode of onset is very common, and the early manifestation may be irritability of the stomach with vomiting or a type of acid dyspepsia with eructations. In young girls (and in children) with this dyspepsia there is very frequently a pronounced anæmia, and the patient complains of palpitation of the heart, increasing weakness, slight afternoon fever, and amenorrhœa.

(c) **MALARIAL SYMPTOMS.**—In some cases the onset of pulmonary tuberculosis is with symptoms which suggest malarial fever. The patient has repeated paroxysms of chills, fevers, and sweats, which may recur with regularity. In districts in which malaria prevails there is no more common mistake than to confound the initial rigors of pulmonary tuberculosis with it.

(d) **WITH PLEURISY.**—The first symptoms may be from a dry pleurisy over an apex, with persistent friction murmur. In other instances the pulmonary symptoms follow an attack of pleurisy with effusion. The exudate gradually disappears, but cough persists, the patient becomes feverish, and signs of disease at one apex gradually become manifest. About one-third of all cases of pleurisy with effusion subsequently have pulmonary tuberculosis.

(e) **WITH LARYNGEAL SYMPTOMS.**—The primary localization may be in the larynx, though in a majority of the instances in which huskiness and laryngeal symptoms are the first noticeable features there are foci already existing in the lung. The group in which throat and larynx symptoms precede the manifestations of pulmonary tuberculosis is a very important one.

(f) **ONSET WITH HÆMOPTYSIS.**—Frequently the first indication is a brisk hæmorrhage from the lungs, following which the pulmonary symptoms may come on with great rapidity. In other cases the hæmoptysis recurs, and it

may be months before the symptoms become well established. In a majority of these cases the local tuberculous lesion exists at the date of the hæmoptysis. Blood-streaked sputum may have the same significance.

(g) WITH TUBERCULOSIS OF THE CERVICO-AXILLARY GLANDS.—Preceding the onset of pulmonary disease for months, or even years, the lymph-nodes of the neck or of the neck and axilla of one side may be enlarged. These cases are of importance because of the latency of the pulmonary lesions and in such patients the corresponding apex of the lung may be extensively involved.

(h) WITH NERVOUS SYMPTOMS.—Malaise, fatigue and indefinite nervous disturbances with loss of weight may be the marked features and suggest neurasthenia or hyperthyroidism.

(i) BRONCHIAL SYMPTOMS.—In by far the largest number of all cases the onset is with a *bronchitis*, or, as the patient expresses it, a neglected cold. There has been, perhaps, a liability to catch cold easily or the patient has been subject to naso-pharyngeal catarrh; then, following some unusual exposure, a cough begins, which may be frequent and irritating. The examination of the lungs may reveal localized moist sounds at one apex and perhaps wheezing bronchitic râles in other parts. In a few cases the early symptoms are suggestive of asthma with marked wheezing and diffuse piping râles.

(j) MISCELLANEOUS GROUP.—(1) Following acute infections, such as influenza. (2) With or after pregnancy. (3) After an operation in which ether anæsthesia was used. (4) In association with ischio-rectal abscess and fistula-in-ano. In all of these an inactive process may be rendered active.

Symptoms.—In discussing the symptoms it is usual to divide the disease into three periods: the first embracing the time of the growth and development of the tubercles; the second, when they soften; and the third, when there is a formation of cavities. Unfortunately, these anatomical stages can not be satisfactorily correlated with corresponding clinical periods, and a patient in the third stage with a well-marked cavity may be in a better condition and with greater prospects of recovery than a patient in the first stage with diffuse consolidation. It is therefore better perhaps to disregard them altogether.

GENERAL SYMPTOMS.—*Fever*.—It is well to bear in mind that the temperature varies slightly in normal individuals, and the afternoon range may be 99° F. The difference between the mouth and rectal temperature may be a full degree, and in young full-blooded persons, in the nervous, and after exercise the normal rectal temperature may be 100.5° or even 101° F. To get a correct idea of the temperature range in pulmonary tuberculosis it is necessary to make observations every two hours at first. The usual 8 A. M. and 8 P. M. record is, in a majority of the cases, very deceptive, giving neither the minimum nor maximum. The former usually occurs between 2 and 6 A. M., and the latter between 2 and 6 P. M. In a tuberculous female there is often an increase of fever at the time of menstruation.

Fever, one of the earliest and most important symptoms, is due to the effect of the toxins or materials absorbed from the tuberculous focus. Later the hectic fever is caused in part by the absorption of the bacterial products of other organisms. It is an auto-inoculation comparable with the fever produced by an injection of tuberculin. Anything that stimulates the local lymph and blood flow favors the discharge of the toxins and causes fever. A patient

at rest may be afebrile; after exercise the temperature may be 102.5° , due to auto-inoculation. In acute cases the fever is more or less continuous, resembling that of typhoid fever or pneumonia, with slight morning remissions. It may set in with a chill and be followed by sweats, and there are cases with a marked intermittent pyrexia from the onset. As a rule, the degree of activity of the local process may be gauged by the persistency and the range of the fever; and favorable cases are those in which the fever yields rapidly

No. 549 White, Dixon. *Phthisis*. ADMITTED November 21st 1889. WARD 24

CHART V.—THREE DAYS. CHRONIC TUBERCULOSIS.

to rest. In a few cases progress of the local disease continues and may even be rapid without fever. The temperature of consumptives is easily influenced by trivial causes which would not affect a normal person, such as mental excitement, exercise, etc. The patient is usually aware of fever and may feel more comfortable with a temperature of 101° . Except the sweating, there are rarely any unpleasant feelings connected with it.

With breaking down of the lung-tissue and formation of cavities, associated as these processes always are with suppuration and mixed infection, the fever assumes a characteristically intermittent type. For a large part of the day the patient is not only afebrile, but the temperature is subnormal. In the annexed two-hourly chart, from a case of chronic tuberculosis of the lungs, it will be seen that, from 10 p. m. to 8 a. m. or noon, the temperature

continuously fell and went as low as 95°. A slow rise then took place through the late morning and early afternoon hours and reached its maximum between 6 and 10 P. M. As shown in the chart, there were in the three days about forty-three hours of pyrexia and twenty-nine hours of apyrexia. The rapid fall of the temperature in the early morning hours is usually associated with sweating. This typical fever of septic infection is met with when the process of cavity formation and softening is advanced and extending.

Sweating.—Drenching perspirations are common and are one of the most distressing features of the disease. They occur usually with the drop in the fever in the early morning, or at any time in the day when the patient sleeps. They may come on early in the disease, but are more persistent and frequent after cavities have formed. Some patients escape altogether.

The pulse is increased in frequency and usually in proportion to the height of the fever. Even when at rest and afebrile the pulse may be rapid, but the excitement of counting it may increase the rate 20 to 30 beats. The pulse is often remarkably full, soft and compressible; even after recovery it may remain rapid. Pulsation may sometimes be seen in the capillaries and in the veins on the back of the hand.

Emaciation is a pronounced feature, from which the two common names of the disease have been derived. The loss of weight is gradual and, if the disease is extending, progressive. The scales give one of the best indications of the progress. It is most rapid early in the disease, when the patient may lose at the rate of five or six pounds a week; and usually is in direct relation to the intensity and duration of the fever. With the arrest of the progress and the fall in temperature the patient usually begins to regain weight. The average gain in weight of 901 patients at the Adirondack Sanatorium was fourteen pounds (L. Brown). A gain of two pounds a week is satisfactory. Loss of strength may be out of proportion to and quite independent of loss of weight. Early debility may be a marked feature.

LOCAL SYMPTOMS.—*Pain* in the chest may be early and troublesome or absent throughout. It is usually associated with pleurisy, and may be sharp and stabbing in character, and either constant or felt only during coughing. Perhaps the commonest situation is in the lower thoracic zone, though in some instances it is beneath the scapula or referred to the apex. The attacks may recur at long intervals. *Intercostal neuralgia* occasionally occurs in the course of ordinary pulmonary tuberculosis.

Cough is one of the earliest symptoms, and is present in the majority of cases from beginning to end. There is nothing peculiar or distinctive about it. At first dry and hacking, and perhaps scarcely exciting the attention of the patient, it subsequently becomes looser, more constant, and associated with a glairy, muco-purulent expectoration. In the early stages the cough is bronchial in its origin. When cavities have formed it becomes more paroxysmal, and is most marked in the morning or after a sleep. Cough is not a constant symptom, however, and a patient may present himself with well-marked excavation at one apex who declares that he has had little or no cough. So, too, there may be well-marked physical signs, dulness and râles, without expectoration or cough. In well-established cases the nocturnal paroxysms are most distressing and prevent sleep. The cough may be of such persistence and severity as to cause vomiting, and the patient becomes emaciated from

loss of food—Morton's cough (*Phthisiologia*, 1689, p. 101). The laryngeal complications give a peculiar husky quality to the cough, and when erosion and ulceration have proceeded far in the vocal cords the cough becomes much less effective.

Sputum.—This varies greatly in amount and character with the different stages. There are patients with well-marked signs at one apex, with slight cough and moderately high fever, without a trace of expectoration. So, also, there are instances with extensive consolidation (caseous pneumonia) and high fever, but without enough expectoration to enable an examination for bacilli to be made. In the early stage of pulmonary tuberculosis the sputum is chiefly catarrhal and has a glairy, sago-like appearance, due to the presence of alveolar cells which have undergone myeline degeneration. There is nothing distinctive or peculiar in this form of expectoration, which may persist for months without indicating serious trouble. The earliest trace of characteristic sputum may show the presence of small grayish or greenish-gray purulent masses. These are always suggestive and should be picked out for microscopic examination. As softening comes on, the expectoration becomes more profuse and purulent, but may still contain a considerable quantity of alveolar epithelium. Finally, when cavities exist, the sputum assumes the so-called nummular form; each mass is isolated, flattened, greenish-gray in color, quite airless, and, when spat into water, sinks to the bottom.

By the microscopic examination of the sputum we determine whether the process is tuberculous, and whether softening has occurred. The bacilli in stained preparations are seen as elongated, slightly curved, red rods, sometimes presenting a beaded appearance. They are frequently in groups of three or four, but the number varies considerably. Only one or two may be found in a preparation, or, in some instances, they are so abundant that the entire field is occupied. Repeated examinations may be necessary.

The continued presence of tubercle bacilli in the sputum is an infallible indication of the existence of tuberculosis. One or two may possibly be due to accidental inhalation. A number may come from a spot of softening 3 by 3 cm. In the nummular sputa of later stages the bacilli, are very abundant.

Elastic tissue may be derived from the bronchi, the alveoli, or from the arterial coats; and naturally its appearance will vary with the locality from which it comes. In the examination for this it is not necessary to boil the sputum with caustic potash. In almost all instances if the sputum is spread in a sufficiently thin layer the fragments of elastic tissue can be seen with the naked eye. The thick, purulent portions are placed upon a glass plate 15 x 15 cm. and flattened into a thin layer by a second glass plate 10 x 10 cm. In the compressed layer between the glass plates any fragments of elastic tissue show on a black background as grayish-yellow spots and can be examined under a low power or the uppermost piece of glass is slid along until the fragment is exposed, when it is picked out and placed upon the ordinary slide. Fragments of bread, etc., may present an opaque white appearance, but with a little practice they can readily be recognized. Fragments of epithelium from the tongue, infiltrated with micrococci, are more deceptive, but the microscope shows the difference.

The bronchial elastic tissue forms an elongated network, or two or three long, narrow fibres are found close together. From the blood-vessels a some-

what similar form may be seen and occasionally a distinct sheeting is found as if it had come from the intima of a good-sized artery. The elastic tissue of the alveolar wall is quite distinctive, the fibres are branched and often show the outline of the arrangement of the air-cells. The elastic tissue from bronchi or alveoli indicates extensive erosion of a tube and softening of the lung-tissue.

Another occasional constituent of the sputum is blood, which may be present as the chief characteristic of the expectoration in hæmoptysis or may simply tinge the sputum. In chronic cases with large cavities, in addition to bacteria, various forms of fungi may be found, of which the aspergillus is the most important. *Sarcinæ* may also occur.

Albumin Reaction.—Albumin is found in the sputum in a majority of cases and its continued absence is evidence against tuberculosis. It occurs in other destructive conditions.

Calcareous Fragments.—Formerly a good deal of stress was laid upon their presence in the sputum, and Morton described a phthisis *a calculis in pulmonibus generatis*. Bayle also described a separate form of *phthisis calculeuse*. The size of the fragments varies from a small pea to a large cherry. As a rule, a single one is ejected; sometimes large numbers are coughed up in the course of the disease. They are formed in the lung by the calcification of caseous masses, and it is said also occasionally in obstructed bronchi. They may come from the bronchial glands by ulceration into the bronchi, and there is a case on record of suffocation in a child from this cause.

The daily ~~amount of~~ expectoration varies. In rapidly advancing cases, with much cough, it may reach as high as 500 c. c. in the day. In cases with large cavities the chief amount is brought up in the morning. The expectoration of tuberculous patients usually has a heavy, sweetish odor, and occasionally it is fetid, owing to decomposition in the cavities.

Hæmoptysis.—One of the most famous of the Hippocratic axioms says, "From a spitting of blood there is a spitting of pus." The older writers thought that the phthisis was directly due to the inflammatory or putrefactive changes caused by the hæmorrhage into the lung. Morton, however, in his interesting section, *Phthisis ab Hæmoptœ*, rather doubted this sequence. Laennec and Louis, and later Traube, regarded the hæmoptysis as an evidence of existing disease of the lung. From the accurate views of Laennec and Louis the profession was led away by Graves, and particularly by Niemeyer, who held that the blood in the air-cells set up an inflammatory process, a common termination of which was caseation. Since Koch's discovery we have learned that many cases in which the physical examination is negative show, either during the period of hæmorrhage or immediately after it, tubercle bacilli in the sputum, so that opinion has veered to the older view, and we regard hæmoptysis as an indication of existing disease. In young, apparently healthy, persons cases of hæmoptysis may be divided into three groups. In the first the bleeding has come on without pneumonia, without overexertion or injury, and there is no family history of tuberculosis. The physical examination is negative, and the examination of the sputum at the time of the hæmorrhage and subsequently shows no tubercle bacilli. Such instances are not uncommon, and, though one may strongly suspect tuberculosis, yet the individuals may retain good health and have no further

trouble. Of 386 cases of hæmoptysis noted by Ware in private practice 62 recovered, and pulmonary disease did not subsequently occur.

In a second group individuals apparently in perfect health are suddenly attacked, perhaps after a slight exertion or during some athletic exercises. The physical examination is negative, but tubercle bacilli are found sometimes in the bloody sputum, more frequently a few days later.

In a third set of cases the individuals have been in failing health for a month or two, but the symptoms have not been urgent and perhaps not noticed. Physical examination shows the presence of well-marked tuberculous disease, and there are both tubercle bacilli and elastic tissue in the sputum.

An interesting study of hæmoptysis, particularly in its relation to tuberculosis, was made in the Prussian army by Stricker. During the five years 1890-'95 there were 900 cases admitted to the hospitals; in 480 the hæmorrhage came on without recognizable cause. Of these, 417 cases, 86 per cent, were certainly or probably tuberculous but in only 221 was the evidence conclusive. In a second group of 213 cases the hæmorrhage came on during military exercise, and of these 75 patients were shown to be tuberculous. In 118 cases the hæmorrhage followed special exercises, as in the gymnasium or riding or swimming. In 24 cases it occurred during the exercise of the voice in singing or in giving command or in the use of wind instruments. In 24 cases the hæmorrhage followed trauma, either a fall or a blow upon the thorax. In 7 of these tuberculosis was positively present, and in 6 other cases there was a strong probability of its existence. Among the conclusions which Stricker draws the following are the most important: namely, that soldiers attacked with hæmoptysis without special cause are in at least 86.8 per cent. tuberculous. In the cases in which hæmoptysis follows special exercises, at least 74.4 per cent. are tuberculous. In the cases which come on during swimming or as a consequence of direct injury to the thorax about one-half are not associated with tuberculosis.

Hæmoptysis occurs in from 60 to 80 per cent. of all cases of pulmonary tuberculosis and as an initial symptom in about 10 per cent. It is more frequent in males than in females. In a majority of all cases the bleeding recurs. Sometimes it is a special feature throughout the disease, so that a hæmorrhagic form has been recognized. The amount of blood brought up varies from a couple of drams to a pint or more. In 69 per cent. of 4,125 cases of hæmoptysis at the Brompton Hospital the amount brought up was under half an ounce.

A distinction may be drawn between hæmoptysis early in the disease and that which occurs in the later periods. In the former the bleeding is usually slight, is apt to recur, and fatal hæmorrhage is very rare. In these cases the bleeding is usually from small areas of softening or from erosions in the bronchial mucosa. In the later periods, after cavities have formed, the bleeding is, as a rule, more profuse and is more apt to be fatal. Single large hæmorrhages, proving quickly fatal, are very rare, except in advanced stages when the bleeding comes from an erosion of a good-sized vessel in the wall of a cavity or from the rupture of an aneurism of a pulmonary vessel.

Hæmoptysis, as a rule, sets in suddenly. Without any warning the patient may notice a warm salt taste and the mouth fills with blood. It may come up with a slight cough. The total amount may not be more than a few

drams, and for a day or two the patient may spit up small quantities. When a large vessel is eroded or an aneurism bursts, the amount of blood brought up is large, and in the course of a short time a pint or two may be expectorated. Fatal hæmorrhage may occur into a very large cavity without any blood being coughed up. The character of the blood is, as a rule, distinctive. It is frothy, mixed with mucus, generally bright red in color, except when large amounts are expectorated, and then it may be dark. The sputum may remain blood-tinged for some days, or there are brownish-black streaks in it, or friable nodules consisting entirely of blood-corpuscles may be coughed up. Blood moulds of the smaller bronchi are sometimes expectorated.

The microscopic examination of the sputum in hæmorrhage cases is most important. If carefully spread out, there may be noted, even in an apparently pure hæmorrhagic mass, little portions of mucus from which bacilli or elastic tissue may be obtained. Flick and others have called attention to the frequency with which hæmoptysis is associated with the appearance or an increase of pneumococci and influenza bacilli in the sputum.

Dyspnœa is not common in ordinary tuberculosis. The greater part of one lung may be diseased and local trouble exist at the other apex without any shortness of breath. Even in the paroxysms of high fever the respirations may not be much increased. Dyspnœa occurs (a) with the rapid extension in both lungs of a broncho-pneumonia; (b) with the occurrence of miliary tuberculosis; (c) sometimes with pneumothorax; (d) in old cases with much emphysema, and it may be associated with cyanosis; (e) in cases with marked adhesions to the diaphragm; (f) in long-standing cases, with contracted apices or great thickening of the pleura, the right heart is enlarged, and the dyspnœa may be cardiac; and (g) with acute pleurisy or large effusion.

PHYSICAL SIGNS.—(a) *Inspection*.—The shape of the chest is often suggestive, though the disease may be found in chests of any build. Practically, however, in a considerable proportion of cases the thorax is long and narrow, with wide intercostal spaces, the ribs more vertical in direction, and the costal angle narrow. The scapulæ are "winged," a point noted by Hippocrates. Another common type of chest is that which is flattened in the antero-posterior diameter. The costal cartilages may be prominent and the sternum depressed. The shoulder, the nipple or the scapula on the affected side may be lower. Asymmetry of the scapulæ is often seen. Inspection of the back is always important. There may be muscular atrophy, especially of the trapezius. Special examination should be made of the clavicular regions to see if one clavicle or if the spaces above or below it are more marked. Defective expansion at one apex is an early and important sign. The condition of expansion of the lower zone of the thorax may be well estimated by inspection. The condition of the præcordia should be noted, as a wide area of impulse, particularly in the second, third, and fourth interspaces, often results from disease of the left apex. From a point behind the patient, looking over the shoulders, one can often better estimate the relative expansion of the apices. Atrophy of the muscles of the shoulder-girdle on the affected side is common, and slight scoliosis may be present. Movement may be restricted on the affected side, particularly at the apex. Pleurisy with adhesions or with effusion, fibrosis, and pneumonic consolidation may limit the movement of one side. The Litten phenomenon (seen best

on the right side) may be restricted in extent or absent. The chest expansion may be much reduced.

(b) *Palpation*.—Deficiency in expansion can be gauged by placing the hands in the subclavicular spaces and then in the lateral regions of the chest and asking the patient to draw slowly a full breath. Standing behind the patient and placing the thumbs in the supraclavicular and the fingers in the infraclavicular spaces one can judge accurately as to the relative mobility. Disease at an apex, though early and before dulness is marked, may be indicated by deficient expansion. There may be tenderness above the clavicle and in the supra-scapular region. The tactile fremitus is increased wherever there is local growth of tubercle or extensive caseation. In comparing the apices it is important to bear in mind that normally the fremitus is stronger over the right than the left. In the later stages, when cavities form, the tactile fremitus is usually much exaggerated over them. When the pleura is greatly thickened the fremitus may be diminished.

(c) *Percussion*.—Tubercles, inflammatory products, fibroid changes, and cavities produce important changes in the pulmonary resonance. There may be localized disease, even of some extent, without much alteration, as when the tubercles are scattered there is air-containing tissue between them. If there is local emphysema the note may be hyperresonant. In early stages percussion may be negative, 28 out of 201 in L. Brown's series. It requires a fair-sized area of infiltration to cause a change in the percussion note, 4 x 6 cm., according to Cornet. One of the earliest and most valuable signs is defective resonance upon and above a clavicle. In a considerable proportion of all cases the dulness is first noted in these regions. The comparison between the two sides should be made also when the breath is held after a full inspiration, as the defective resonance may then be more clearly marked. In the early stages the percussion note is usually higher in pitch, and it may require an experienced ear to detect the difference. In recent consolidation from caseous pneumonia the percussion note often has a tympanitic quality. Confusing and varying signs are sometimes due to areas of collapse or a small pneumo-thorax. A wooden dulness is rarely heard except in old cases with extensive fibroid change. Over large, thin-walled cavities at the apex the cracked-pot sound may be obtained. Percussion should be carefully done in the supraspinous fossæ and the interscapular space, as they correspond to very important areas early involved in the disease. By light percussion along the border of the trapezius and in the supraclavicular and supraspinous fossæ, areas of apical resonance may be mapped out (Kronig's apical resonance zones). Under normal conditions the areas are equal on the two sides. Consolidation or retraction of an apex causes definite narrowing of the zone on the affected side. The procedure gives valuable information in the early stage of infiltration. Goldscheider uses a special pleximeter and percusses out the borders of the apex of the lung projecting above the clavicle. The method is less satisfactory than that of Kronig. In cases with numerous isolated cavities at the apex, without much fibroid tissue or thickening of the pleura, the percussion note may show little change, and the contrast between the signs obtained on auscultation and percussion is most marked. In direct percussion, particularly in thin patients over the pectorals, one frequently sees the phenomenon known as *myoidema*, a local contraction of the muscle

causing bulging, which persists for a variable period and gradually subsides. It has no special significance.

(d) *Auscultation*.—Feeble breath-sounds are among the most characteristic early signs and it is well at first always to compare carefully the corresponding points on the two sides of the chest without asking the patient either to draw a deep breath or to cough. With early apical disease the inspiration on quiet breathing may be scarcely audible. Expiration is usually prolonged. On the other hand, there are cases in which the earliest sign is a harsh, rude, respiratory murmur. On deep breathing it is frequently to be noted that inspiration is jerking or wavy, the so-called “cog-wheel” rhythm; which, however, is by no means confined to tuberculosis. With extension of the disease the inspiratory murmur is harsh, and, when consolidation occurs, whiffing and bronchial. With these changes in the character of the murmur there are râles. The patient should first breathe quietly, then take a full breath, and then cough. When heard with quiet breathing, if they persist and are present in one area only, they are of great importance. The fine rustling crepitus heard when the patient first takes a deep breath is of no moment. It may also be present at the bases. Râles at the end of a deep inspiration which disappear on repeated breathing may be suspicious but are not positive. Râles which are brought out by coughing (most useful during expiration), which persist, and are repeatedly heard at the same spot are of the greatest importance. It is of equal import when moist, clicking râles are present with change in the percussion note. Attention to these rules will save many of the unnecessary diagnoses of pulmonary tuberculosis made on auscultatory signs alone.

When softening occurs the râles are louder and have a bubbling, sometimes a characteristic clicking quality. These “moist sounds,” as they are called, when associated with change in the percussion resonance are extremely suggestive. When cavities form the râles are louder, more gurgling, and resonant in quality. When there is consolidation of any extent the breath-sounds are tubular, and in the large excavations loud and cavernous, or have an amphoric quality. In the unaffected portions of the lobe and in the opposite lung the breath-sounds may be harsh. The vocal resonance is usually increased in all stages of the process, and bronchophony and pectoriloquy are met with in the regions of consolidation and over cavities. Pleuritic friction may be present at any stage and sometimes occurs very early. There are cases in which it is a marked feature throughout. When the lappet of lung over the heart is involved there may be a pleuro-pericardial friction, and when this area is consolidated there may be curious clicking râles synchronous with the heart-beat, due to the compression by the heart of this portion with expulsion of air from it. An interesting sign in thin-chested persons, in nervous patients, and often in early pulmonary tuberculosis is the so-called cardio-respiratory murmur, a whiffing systolic murmur due to the propulsion of air out of the tubes by the impulse of the heart. It is best heard during inspiration and in the antero-lateral regions of the chest.

A systolic murmur is frequently heard in the subclavian artery on either side, the pulsation of which may be very visible. The murmur is in all probability due to pressure on the vessels by the thickened pleura.

The signs of cavity may be here briefly enumerated.

(1) When there is not much thickening of the pleura or condensation of the surrounding lung-tissue, the percussion sound may be full and clear, resembling the normal note. More commonly there is dulness or a tympanitic quality which may at times be purely amphoric. The pitch of the percussion note changes over a cavity when the mouth is opened or closed (Wintrich's sign), or it may be brought out more clearly on change of position. The cracked-pot sound is obtainable over tolerably large cavities with thin walls or when one cavity is above another. It is best elicited by a firm, quick stroke, the patient at the time having the mouth open. (2) On auscultation there are various grades of modified breathing—blowing or tubular, cavernous or amphoric. There may be a curiously sharp hissing sound, as if air was passing from a narrow opening into a wide space. In large cavities both inspiration and expiration may be typically amphoric. There are coarse bubbling râles which have a resonant quality, and on coughing may have a metallic or ringing character or be loud and gurgling. In large thin-walled cavities, and more rarely in medium-sized cavities, surrounded by recent consolidation, the râles may have a distinctly amphoric echo, simulating those of pneumothorax. There are dry cavities in which no râles are heard. The vocal resonance is greatly intensified, and whispered bronchophony is clearly heard. In large apical cavities the heart-sounds are well heard, and occasionally there may be an intense systolic murmur, probably always transmitted to and not produced in the cavity itself. In large excavations of the left apex the heart impulse may cause gurgling sounds or clicks synchronous with systole. They may even be heard at a little distance from the chest wall. A large cavity with smooth walls and thin fluid contents may give the succussion sound when the trunk is abruptly shaken (Walshe), and even the coin sound may be obtained.

Pseudo-cavernous signs may be caused by an area of consolidation near a large bronchus. The condition may be most deceptive—the high-pitched or tympanitic percussion note, the tubular or cavernous breathing, and the resonant râles simulate closely the signs of cavity.

3. Fibroid Tuberculosis

In their monograph on Fibroid Diseases of the Lung, Clark, Hadley, and Chaplin make the following classification: 1. Pure fibroid—a condition in which there is no tubercle. 2. Tuberculo-fibroid disease—a condition primarily tuberculous, but which has run a fibroid course. 3. Fibro-tuberculous disease—a condition primarily fibroid, but which has become tuberculous. The tuberculo-fibroid form may come on gradually as a sequence of a chronic tuberculous broncho-pneumonia or follow a chronic tuberculous pleurisy. In other instances the process supervenes upon ordinary ulcerative tuberculosis. The disease becomes limited to one apex, the cavity is surrounded by dense fibrous tissue, the pleura is thickened, and the lower lobe is gradually invaded by the sclerotic change. Ultimately a picture is produced little different from the condition known as fibrosis of the lungs. It may even be difficult to say that the process is tuberculous, but in advanced cases the bacilli are usually present in the walls of the cavity at the apex, or old, encapsulated caseous areas are present, or there may be tubercles at the apex of the other lung

and in the bronchial glands. Dilatation of the bronchi is present; the right ventricle, sometimes the entire heart, is hypertrophied.

The disease is chronic, lasting from ten to twenty or more years, during which time the patient may have fair health. The chief *symptoms* are cough, often paroxysmal in character and most marked in the morning, and dyspnoea on exertion. The expectoration is purulent, and in some instances, when the bronchiectasis is extensive, fetid. There is rarely any fever.

The physical signs are very characteristic. The chest is sunken and the shoulder lower on the affected side; the heart is often displaced. If the left lung is involved there may be an unusually large area of cardiac pulsation in the third, fourth, and fifth interspaces. Heart murmurs are common. There are dulness and deficient tactile fremitus over the affected side, except over cavities where fremitus is increased. At the apex there may be well-marked cavernous sounds; at the base, distant bronchial breathing. In some cases the other lung becomes involved, or the patient has repeated attacks of hæmoptysis, in one of which he dies. Amyloid degeneration may take place; dropsy frequently supervenes from failure of the right heart.

Complications of Pulmonary Tuberculosis

In the Respiratory System.—The larynx is rarely spared in chronic pulmonary tuberculosis. The first symptom may be huskiness of the voice. There are pain, particularly in swallowing, and a cough which is often wheezing, and in the later stages very ineffectual. Aphonia and dysphagia are most distressing features of the laryngeal involvement. When the epiglottis is seriously diseased and the ulceration extends to the lateral wall of the pharynx, the pain in swallowing may be intense, owing to imperfect closure of the glottis; there may be coughing spells and regurgitation of food through the nostrils. Bronchitis and tracheitis are almost invariable accompaniments.

Pneumonia is an occasional complication of pulmonary tuberculosis. It usually runs a perfectly normal course, but resolution may be delayed, and one is in doubt as to the presence of a simple or a tuberculous pneumonia. In some cases pneumonia is a terminal complication.

Emphysema of the uninvolved portions of the lung is common, rarely producing any special symptoms. There are, however, cases of chronic tuberculosis in which emphysema dominates the picture, and in which the condition comes on slowly during a period of many years. General subcutaneous emphysema, met with in a few rare cases, is due either to perforation of the trachea or to the rupture of a cavity adherent to the chest wall.

Collapse of the lung may occur with hæmoptysis or pneumothorax. Varying grades of distress, acute dyspnoea, cyanosis and tachycardia may result.

Gangrene of the lung is an occasional event, due in almost all instances to sphacelus in the walls of the cavity, rarely in the lung-tissue itself.

Complications in the Pleura.—A dry pleurisy is a very common accompaniment of the early stages of tuberculosis. It is always a conservative, useful process. In some cases it is very extensive, and friction murmurs may be heard over the sides and back. The cases with dry pleurisy and adhesions are much less liable to the dangers of pneumothorax. Pleurisy with effusion

more commonly precedes than occurs in the course of pulmonary tuberculosis. Still, there are cases in which a sero-fibrinous effusion arises in the course of the chronic disease. In some it is a special feature, and seems to favor chronicity. A patient may during a period of four or five years have signs of local disease at one apex with recurring effusion in the same side. Owing to adhesions in different parts of the pleura, the effusion may be encapsulated. *Hæmorrhagic* effusions, not uncommon with tuberculous pleurisy, are comparatively rare in pulmonary tuberculosis. Chyliform or milky exudates are sometimes found. Purulent effusions are not frequent apart from pneumothorax. An empyema, however, may occur in the course of the disease or as a sequence of a sero-fibrinous exudate.

Pneumothorax is an extremely common complication. Of 49 cases at the Johns Hopkins Hospital, 23 were tuberculous (Emerson). It may prove fatal in twenty-four hours. In other instances a pyo-pneumothorax follows and the patient lingers for weeks or months. In some patients it seems to have a beneficial effect.

Small Pneumothorax.—Barlow and Thompson have drawn attention to its frequency and to the importance of its recognition in the interpretation of puzzling physical signs. The pneumothorax may be superficial, interlobar or mediastinal. The symptoms are very variable. The onset may be sudden with pain, dyspnoea and bloody sputum. The signs are variable and depend on the size of the pneumothorax, the amount of collapse of the lung, and the extent of pleural exudate. Previous signs of lung involvement may disappear and suggest improvement. There may be deviation of the trachea to the affected side (the opposite of large pneumothorax). The percussion note shows combinations of tympany and dullness, depending on the amount of air, the pleural exudate and the extent of collapse. A superficial pneumothorax gives decreased breath sounds and exudate cuts them off. A friction rub may be heard in adjoining areas. The whispered voice is often high pitched and amphoric and near the area there may be bronchophony. There are usually fine râles heard over the area of collapse. The X-ray diagnosis is difficult and requires special methods and training.

Changes in Other Organs.—(a) *Cardio-vascular*.—The retraction of the left upper lobe exposes a large area of the heart and in thin-chested subjects there may be marked visible pulsation. Sometimes with much retraction of the left upper lobe the heart is drawn up. A systolic murmur over the pulmonary area and in the subclavian arteries is common in all stages. Apical murmurs are not infrequent and may be extremely rough and harsh without necessarily indicating that endocarditis is present. The association of heart disease with tuberculosis is not, however, very uncommon. There were 12 instances of endocarditis in 216 autopsies. The arterial tension is usually low and the capillary resistance lessened so that the pulse is often full and soft even in the later stages. *Phlebitis* may occur early, usually in the legs and more often in the saphenous than in the femoral vein. It is usually gradual in onset, does not cause severe pain, and œdema is slight unless the femoral vein is involved.

(b) *Blood*.—The early *anæmia* is often more apparent than real and severe *anæmia* is rare. The blood-plates are, as a rule, enormously increased and are seen in the withdrawn blood as the so-called Schultze's granule masses. Without any significance, they are of interest chiefly from the fact that every

few years some tyro announces their discovery as a new diagnostic sign of tuberculosis. The leucocytes are increased, particularly in the later stages. The percentage of lymphocytes is higher in the milder and more chronic cases. The value of the Arneth index is doubtful.

(c) Gastro-intestinal System.—The tongue is usually furred, but may be clean and red. Small aphthous ulcers are sometimes distressing. A red line on the gums, a symptom to which at one time much attention was paid as a special feature of tuberculosis, occurs in other cachetic states. Extensive tuberculous disease of the pharynx, associated with a similar affection of the larynx, may interfere seriously with deglutition and prove a very distressing and intractable symptom. The saliva has full digestive powers.

Tuberculosis of the stomach is rare. Ulceration may occur as an accidental complication and multiple catarrhal ulcers are not uncommon. Interstitial and parenchymatous changes in the mucosa are common (possibly associated with the venous stasis) and lead to atrophy, but these cannot always be connected with the symptoms, and may be found when not expected. On the other hand, when the gastric symptoms have been most persistent the mucosa may show very little change. It is impossible always to refer the anorexia, nausea, and vomiting to local conditions. The fever and the neurotic influences must be taken into account, as they play an important rôle. There is interference with both the secretory and motor functions early in the course. Hyperacidity is rare (Mohler and Funk).

Anorexia is often marked at the onset; there may be positive loathing for food, and even small quantities cause nausea. Sometimes, without any nausea or distress after eating, the feeding of the patient is a daily battle. When practicable, forced alimentation is of great benefit in such cases. Nausea and vomiting, though occasionally troublesome at an early period, are more marked in the later stages. The latter may be caused by the severe attacks of coughing. S. H. Habershon refers to four causes of vomiting: (1) Central, as from tuberculous meningitis; (2) pressure on the vagi by caseous glands; (3) stimulation from the peripheral branches of the vagus, either pulmonary, pharyngeal, or gastric; and (4) mechanical causes.

Of the intestinal symptoms diarrhoea is the most serious. It may come on early, but is more usually a symptom of the later stages, and is associated with ulceration, particularly of the large bowel. Extensive ulceration of the ileum may exist without any diarrhoea. The associated catarrhal condition may account in part for it, and in some instances the amyloid degeneration of the mucous membrane. Perforation occurred in 13 of 475 autopsies in chronic pulmonary tuberculosis.

(d) Nervous System.—(1) Focal lesions are due to coarse tubercles and areas of tuberculous meningo-encephalitis. Aphasia, for instance, may result from the growth of meningeal tubercles in the fissure of Sylvius, or hemiplegia may occur. The solitary tubercles are more common in the chronic tuberculosis of children. (2) Basilar meningitis is an occasional complication. It may be confined to the brain, though more commonly it is a (3) cerebro-spinal meningitis, which may come on in persons without well-marked signs in the chest so that the existence of pulmonary disease is not discovered until the post mortem. (4) Peripheral neuritis, which is not common, may cause an extensor paralysis of the arm or leg, more commonly the latter, with foot-

drop. It is usually a late manifestation. (5) The brachial plexus, close to the pleuro-pulmonary apex, is sometimes involved, either by adhesion to the tuberculous glands in the neighborhood or in the thickening of the tissues about the pleura itself. There may be pains in the arm, trophic disturbances and occasionally paralysis, particularly in the distribution of the lower cord in the plexus. (6) Mental symptoms. It was noted, even by the older writers, that consumptives had a peculiarly hopeful temperament, and the *spes phthisica* forms a curious characteristic of the disease. Patients with extensive cavities, high fever, and too weak to move will often make plans for the future and confidently expect to recover.

Apart from tuberculosis of the brain, there is sometimes in chronic tuberculosis a form of insanity not unlike that which occurs in the convalescence from acute affections.

(e) Eyes.—The conjunctiva is rarely involved. Iritis may occur and not always of the tuberculous variety. Keratitis, choroiditis, scleritis and episcleritis occur. The pupils are often unduly dilated. With apical pleurisy, irregularity of the pupils may be present. Myosis with narrowing of the palpebral fissure and retraction of the eye or mydriasis with associated vasomotor features may be found with small lesions of the apex with pleural involvement.

(f) Hypertrophy of the mammary gland may occur in pulmonary tuberculosis, most commonly in males. It may be only on the affected side. It is a chronic interstitial, non-tuberculous mammitis (Allot). Mastitis adolescentium is not necessarily suggestive of pulmonary tuberculosis.

(g) Genito-urinary System.—The urine presents no special peculiarities but fever has a marked influence upon it. Albumin is met with frequently and may be associated with the fever or is the result of definite changes in the kidneys. Tubercle bacilli may be present in the urine without any disease of the kidney. Amyloid disease of the kidneys is not uncommon. Its presence is shown by albumin and casts, and sometimes by a great increase in the amount of urine. In other instances there is dropsy, and the patients have the characteristic features of chronic nephritis.

Pus in the urine may be due to disease of the bladder or of the pelves of the kidneys. In some instances the entire urinary tract is involved. In pulmonary tuberculosis, however, extensive tuberculous disease is rarely found in the urinary organs. Hæmaturia is not very common and may occur occasionally as a result of congestion of the kidneys, and pass off, leaving the urine albuminous. In other instances it results from disease of the pelvis or of the bladder, and is associated either with early tuberculosis or more commonly with ulceration. In a medical clinic the routine inspection of the testes for tubercle will save two or three mistakes a year. Aménorrhœa is common in women. Bartholin's gland may show tuberculous infection.

(h) Cutaneous System.—The skin is often dry and harsh. Local tubercles occasionally occur on the hands. There may be pigmentary staining, the *chloasma phthisicorum*, which is more common when the peritoneum is involved. Upon the chest and the back the brown stains of *pityriasis versicolor* are very frequent. The hair of the head and beard may become dry and lanky. The terminal phalanges, in chronic cases, become clubbed and the nails incurvated—the Hippocratic fingers. Landouzy called attention to a

curious bending, usually of the ring and little fingers, which permits of flexion, but not of extension—a condition which he calls *camptodactyly*. A remarkable and unusual complication is general emphysema, which may result from ulceration of an adherent lung or perforation of the larynx.

Diagnosis of Pulmonary Tuberculosis

With fever, well-marked physical signs and bacilli in the sputum, no disease is more easily diagnosed. Successful treatment depends largely upon early diagnosis, and special attention must be paid to the obscure, variable, and uncertain symptoms and signs of the initial stage. The active crusade against the disease has made both the public and the profession more alert, but some have, as so often happens, gone to an extreme, and are apt to see early tuberculosis in trivial complaints. This is based on the experience of cases seen in consultation, and is borne out by the records of institutions. Hamman, in charge of the Phipps Tuberculosis Dispensary of the Johns Hopkins Hospital, makes the interesting confession that in the early days, when they depended on slight physical signs and the tuberculin reaction, there were innumerable early cases, but with a wider experience and greater confidence in clinical symptoms the outlook on these borderland cases has changed completely, and they are found to keep well under the ordinary conditions of life, in spite of the persistence of slight abnormal signs. How important this feature of tuberculosis work has become is indicated by the figures for the first year at the Tuberculosis Dispensary of the Radcliffe Infirmary. Of 580 cases, all sent by physicians, 243 were found not to be tuberculous! One lesson from the work of the past few years is that we should pay more attention to symptoms than to physical signs. The following are the points of special importance in the diagnosis of early cases:

History.—Tuberculosis in the family, “*Phthisical habitus*,” exposure to infection, special debilitating circumstances, as worry, dissipation, or a chronic illness, pleurisy, “*bronchitis*” which persists, and blood-tinged sputum.

Symptoms.—Loss of weight, loss of strength, marked nervous and physical exhaustion, and anæmia, if progressive and not otherwise accounted for, are of first importance. Fever is both most trustworthy and most fallacious. The thermometer has needlessly condemned many patients to a sanatorium. Regard should be had to the points already mentioned in speaking of the fever. In nervous persons, particularly in flabby young girls, a temperature from 99.5° to 100° may mean nothing, and the rectal temperature is often deceptive: if taken after exercise or excitement it may be a degree and a half above normal. In the case of a flabby, fat girl of ten, with an anxious mother, a foolish nurse, and an alarmist doctor, for months the rectal temperature was taken hourly during the day; the child had been in bed; there was no cough, and the only physical sign a few rustling râles at one apex. The cure followed rapidly on the breaking of the thermometer and getting rid of the nurse. In a suspicious case a two-hour temperature record should be taken during the day for ten days and the influence of exercise upon it carefully estimated. Fever, otherwise unexplained, is always suggestive of tuberculosis but other causes should be excluded; focal infection, syphilis, and genito-urinary tract infection may be overlooked.

A cough is always suspicious in the young, more in the winter than in the summer, and more in the morning than at other times. Throat and sinus conditions should be carefully excluded, particularly the irritation from cigarette smoking. The spitting of blood has been considered and its importance in the diagnosis of tuberculosis is universally recognized. An early hæmoptysis is often helpful, not only for the positive information it gives but for its useful moral effect on the patient. The greater the care with which the bloody sputum is examined the more likely it is that bacilli are found. A short dry cough, especially on exertion, is suspicious.

Sputum.—The patient should be instructed to collect what is expectorated, particularly early in the morning, and everything brought up should be sent. The difficulty in private practice is that it requires a long series of examinations to exclude positively the presence of tubercle bacilli. Time and again with suspicious cases, or in pleurisy with effusion, the clinical clerk has been asked day by day “Any bacilli yet?” and in one instance none were found until the twentieth examination! Of course, in private practice this is impossible, but it is well to bear in mind that one or two negative examinations are not sufficient. Various methods of digesting the sputum and examining the centrifugalized sediment are important when few bacilli are present. The antiformin method introduced by Uhlenhuth is simple and often reveals tubercle bacilli missed by an ordinary examination.

Physical Signs.—These raise the difficulty. At present, so far as the lungs are concerned, the position resembles that of years ago in respect to the heart, when any murmur was regarded as serious. Now, if we see the apex beat within the nipple line and there is no shortness of breath, and the pulse is regular, we discount physical signs and tell the patient to live a rational life. This is what we should do with many cases of suspected early tuberculosis. If the symptoms above dealt with are not present, “discount” the physical signs. These have already been considered: change in the character of the respiratory murmur and the presence of râles are the two most important, as dulness is rarely present in early cases. Altogether too much stress has been laid upon roughened or impure inspiration associated with a few râles. Only upon repeated examinations should a decision be reached. Practically, in these early cases, we have two groups—the one with symptoms and no physical signs, and the other with physical signs and no symptoms. Of the two, the former is of the greater importance.

In regard to the extent of disease in the lung, caution is advisable in patients seen for the first time with fever and acute symptoms. Signs may be found over a large area, but these may be due principally to an acute intercurrent infection and lessen materially in a few days.

Certain conditions may be wrongly diagnosed as tuberculous. Foreign bodies in the bronchi may be a cause of error. In patients with infection of the mouth or throat, tonsillitis, sinusitis, and adenoids, there may be a persistent cough with bronchitis and fever. Recognition and proper treatment of the cause may result in the prompt disappearance of the pulmonary signs. In some cases these non-tuberculous infections cause definite fibroid change. There are certain non-tuberculous chronic bronchial and pulmonary diseases which may be mistaken for tuberculosis. Mycotic infections, spirochetal bronchitis, abscess, neoplasm, sypilis, chronic bronchitis, fibrosis and bronchiectasis

are in this group. It is a good rule that with signs of advanced chronic disease in the lungs and no tubercle bacilli in the sputum, the condition is not likely to be tuberculous. A diagnosis of tuberculosis based on marked lung changes without finding tubercle bacilli in the sputum is often wrong. Atypical forms of pneumonia, disease of the pleura, especially apical, and aneurism may lead one astray. *Pneumococcosis* plus tuberculosis may give great difficulty. Signs in the lungs secondary to *cardiac* disease not infrequently cause error; râles due to circulatory disturbance may be apical as well as basal. Mitral stenosis is the lesion most likely to mislead; the persistence of the lung signs, the occurrence of hæmoptysis and the occasional presence of dulness above the third rib on the left side (Goodman) all contribute to the mistake.

Post-influenzal changes and conditions in soldiers who were gassed often cause difficulty. There may be complaint of general ill health, weakness, cough and pain or discomfort in the chest. Wheezing and shortness of breath with rapid heart action on exertion occur in some. The signs are varied and usually most marked on auscultation, harsh breath sounds, râles of different kinds, usually coarse and on both sides. The X-ray may show much diffuse thickening but no definite local lesion. Fibrosis and emphysema seem to be the important factors in many cases.

Specific Reaction.—*Tuberculin Test.*—This is employed: (1) To determine the presence or absence of tuberculin hypersensitiveness and (2) to elicit a focal reaction. (1) To determine tuberculin hypersensitiveness the cutaneous or intradermal test is used. A positive reaction signifies the presence of a tuberculous lesion but does not prove that the patient has tuberculous disease, in the ordinary sense of the term disease. As a large proportion of adults (60 to 80 per cent.) show tuberculin hypersensitiveness, a positive test has little value in diagnosis. It is more useful in young children but in them it must be interpreted with caution. In the absence of acute or advanced disease a negative test is strong evidence against tuberculosis and therefore of decided value. (2) To elicit a focal reaction the subcutaneous test is employed. An amount of tuberculin sufficient to produce a general reaction must be given and changes in the signs in the local suspected area must be searched for during the reaction. If definite changes occur they indicate that the lesion is tuberculous. This test is not used frequently, as definite signs of a focal reaction are difficult to obtain and the general reaction produced may result in harm. The subcutaneous test should only be done by one experienced in the use of tuberculin. The conjunctival test is no longer used.

Complement Fixation Test.—Unfortunately this has not proved to be of much value in doubtful cases. It may be of help in deciding as to the arrest of the disease.

X-ray Diagnosis.—In skilful hands the study of cases with the Röntgen rays is of great value. In a normal case the radiogram shows a shadow beneath and extending beyond the sternum due to the contents of the mediastinum. Extending from the mediastinum and radiating out into the various lobes is a series of shadows which may be likened to the branches of a tree, the thickest shadow being at the hilum and thinning toward the periphery of the lungs. In diseased conditions changes are seen in the hilum, shadows due to enlarged or calcified glands and to the increase in the fibrous and lymphatic tissues in the mediastinum. The pulmonary vessels with their

contained blood play an important part in the production of the shadow. The X-rays undoubtedly show very early changes in the lungs, but they can not always determine the etiological factor. Much depends on the roentgenologist who examines the plates; with a skilled man the results are of great value. The physician and roentgenologist should examine the plates together. In some cases with signs and positive sputum results the X-ray examination is negative. More than any others, some roentgenologists need the salutary lessons of the dead house to correct their visionary interpretations of shadows.

Concurrent Infections.—It has long been known that in pulmonary tuberculosis organisms other than the specific bacilli are present, particularly the *pneumococcus*, *streptococci* and *staphylococci*, the influenza bacillus, *Micrococcus catarrhalis*, and less frequently *Bacillus pyocyaneus*.

Many cases of pulmonary tuberculosis are combined infections; streptococci and pneumococci may be found in the sputum, and the former have been isolated from the blood. Prudden arrives at the following conclusions: The pulmonary lesions of tuberculosis are subject to variations depending largely on the different modes of distribution of the bacilli, whether by the blood vessels or through the bronchi, and also whether a concurrent infection with other organisms has taken place. The pneumonia complicating tuberculosis may be due to the tubercle bacillus or may follow secondary infection with other germs. An infection by other organisms may be followed by increased fever and an aggravation of the general symptoms. The frequency of these secondary infections and their relative significance are not fully decided. It is probable that the effect of infection with the pus organisms is important in hastening necrosis and softening, and in the chronic cases they doubtless produce in large amounts the toxins which are responsible for many of the symptoms. The work of Hastings indicates that secondary infections are not so important as we had thought, and a study by Radcliffe at the King Edward Sanatorium points in this direction.

Diseases Associated with Pulmonary Tuberculosis.—*Lobar pneumonia* is not a common cause of death. It may occur as a terminal event in the chronic cases or may occur early and be difficult to distinguish from an acute caseous pneumonia. The sputum in the latter is rarely rusty, while the fever in the former is more continuous and higher, but in many cases it is impossible to differentiate between the two conditions.

The association of tuberculosis and *typhoid fever* has been discussed.

Erysipelas not infrequently attacks old *poitrinaires* in hospital wards and almshouses. There are instances in which the attack seems to be beneficial, as the cough lessens and the symptoms ameliorate. It may occasionally prove fatal.

Erythema Nodosum.—Some regard it as a symptom of the disease, a "tuberculide" as the French call it. Guinea-pigs have been successfully inoculated from the lesions but clinically we rarely see any definite association.

The *eruptive fevers*, particularly measles, sometimes precede but rarely occur in the course of pulmonary tuberculosis. In the revaccination of a tuberculous subject the vesicles run a normal course.

Fistula in ano, so often associated with pulmonary tuberculosis, in a majority of such cases is a tuberculous process. The general affection may progress rapidly after an operation.

Heart Disease.—Cardiac hypoplasia seems uncommon in tuberculosis, though it was much referred to by the older writers. It was present in only 3 cases in 1,764 autopsies on tuberculous patients (Norris). Rokitsansky taught that there was an antagonism between valvular lesions and aneurisms and tuberculosis. All forms of congenital heart disease predispose to it, particularly pulmonary stenosis. Mitral stenosis, on the other hand, has a distinctly inhibitory influence and the two conditions are rarely found associated. Endocarditis has been mentioned. A terminal acute tuberculosis, particularly of the serous membranes, is not uncommon in cardio-vascular disease.

In chronic and arrested tuberculosis *arterio-sclerosis* and *phlebo-sclerosis* are not uncommon. Ormerod noted 30 cases of chronic renal disease in 100 post mortems.

Diabetes mellitus.—Among 31,834 cases of tuberculosis there were 151 with glycosuria, and in 1047 autopsies there were 6 cases of diabetes mellitus. The association means an unfavorable prognosis. In treatment the diabetes should be handled in the usual way.

Cancer.—Not often associated with active tuberculosis, many persons dying of cancer show foci of old tuberculosis. There does not seem to be any active antagonism between the diseases.

Peculiarities of Pulmonary Tuberculosis at the Extremes of Life

Old Age.—It is remarkable how common tuberculosis is in the aged, particularly in institutions. McLachlan noted 145 cases in which tuberculosis was the cause of death in old persons in Chelsea Hospital. All were over sixty years of age. The experience at the Salpêtrière is the same. Laennec met with a case in a person over ninety-nine years of age.

At the Philadelphia Hospital, in the bodies of aged persons from the almshouse, it was extremely common to find either old or recent tuberculosis. One patient died at the age of eighty-two with extensive peritoneal tuberculosis. Pulmonary tuberculosis in the aged is usually latent and runs a slow course. The physical signs are often masked by emphysema and by the coexisting chronic bronchitis. The diagnosis may depend entirely upon the discovery of the bacilli and elastic tissue. Tuberculosis is by no means uncommon with senile emphysema. Some of the cases of tuberculosis in the aged are instances of quiescent disease which may have dated from an early period.

Infancy.—The occurrence of acute tuberculosis in children has been mentioned, and also that the disease is occasionally congenital. In Wollstein's study from the New York Babies' Hospital, among 1,131 autopsies in children under four years of age, in 192 tuberculosis was present; the percentage was: first year 1.8 per cent., second year 11 per cent., third year 16 per cent., and fourth year 23 per cent. Chronic ulcerative tuberculosis of the lungs is much more rare than in adults. In Parrot's series of 219 cases in children under three years of age, in only 57 were cavities found in the lungs.

Modes of Death in Pulmonary Tuberculosis

(a) **By asthenia**, a gradual failure of the strength. The end is usually peaceable and quiet, occasionally disturbed by paroxysms of cough. Consciousness is often retained until near the close.

(b) **By asphyxia**, as in some cases of acute miliary and acute pneumonic tuberculosis. In chronic pulmonary tuberculosis it is rarely seen, even when pneumothorax develops.

(c) **By syncope**. This is not common but may happen in patients who insist upon going about when in the advanced stages. There may be, but not necessarily, fatty degeneration of the heart. Rapid syncope may follow hæmorrhage or be due to pulmonary thrombosis or embolism or pneumothorax.

(d) **From hæmorrhage**. The fatal bleeding in chronic tuberculosis is due to erosion of a large vessel or rupture of an aneurism in a pulmonary cavity, most commonly the latter. Of 26 cases analyzed by S. West, in 11 the fatal hæmoptysis was due to aneurism, and, of 35 cases collected by Percy Kidd, aneurism was present in 30. In a case of Curtin's, at the Philadelphia Hospital, the bleeding proved fatal before hæmoptysis occurred, as the eroded vessel opened into a capacious cavity.

(e) **With cerebral symptoms**. Coma may be due to meningitis, less often to uræmia. Death in convulsions is rare. The hæmorrhagic pachymeningitis which occurs in some cases occasionally causes loss of consciousness, but is rarely a direct cause of death. In one of our cases death resulted from thrombosis of the cerebral sinuses with symptoms of meningitis.

V. TUBERCULOSIS OF THE ALIMENTARY CANAL

(a) **Lips**.—Tuberculosis of the lip is very rare. It occurs occasionally as a solid tuberculoma or in the form of an ulcer, either alone or more commonly with laryngeal or pulmonary disease. The ulcer is usually very sensitive and may be mistaken for a chancre or an epithelioma. The diagnosis may be made by inoculation or the examination of a portion for tubercle bacilli. The cheeks, gums and floor of the mouth are very rarely involved. Lupus occasionally extends to the mouth from the skin.

(b) **Tongue**.—The disease begins by an aggregation of small granular bodies on the edge or dorsum. Ulceration proceeds, leaving an irregular sore with a distinct but uneven margin, and a rough, often caseous base. The disease extends slowly and may form an ulcer of considerable size. It may be mistaken for epithelioma and the tongue excised. It is rarely met with except when other organs are involved. The glands of the angle of the jaw are not enlarged and the sore does not yield to iodide of potassium, which are points of distinction between the tuberculous and the syphilitic ulcer. In doubtful cases the inoculation test should be made, or a portion excised for microscopic examination. The ulcer is very indolent.

(c) **Salivary Glands**.—The salivary glands seem to possess a strong relative immunity; a very few cases have been reported.

(d) **Palate**.—Tubercles of the hard or soft palate nearly always follow extension of the disease from neighboring parts. The lesions are usually multiple and ulcerated.

(e) **Tuberculosis of the Tonsils.**—This is mentioned previously. Some claim that the majority of cases of tuberculous cervical glands result from infection with tubercle bacilli which gain admission by the tonsil. There may be infection of the crypts, superficial ulceration or an infiltration with miliary tubercles, that produces hypertrophy which it is impossible to distinguish from ordinary enlargement of the tonsil without microscopic examination.

(f) **Pharynx.**—In extensive laryngeal tuberculosis an eruption of miliary granules on the posterior wall of the pharynx is not very uncommon. In chronic tuberculosis an ulcerative pharyngitis, due to extension of the disease from the epiglottis and larynx, renders deglutition acutely painful. Adenoids of the naso-pharynx may be tuberculous. Macroscopically, they do not differ from the ordinary vegetations in this situation.

(g) **Æsophagus.**—A few instances occur in the literature of tuberculosis of the æsophagus. The condition is a pathological curiosity, except in the slight extension from the larynx, which is not infrequent; but in a case described by Flexner, the ulcer perforated and caused purulent pleurisy. The condition has been considered by Claribel Cone, who described a second case from the Johns Hopkins Hospital (Bulletin, Nov., 1897).

(h) **Stomach.**—Many cases are reported which are doubtful. In 2,000 autopsies at the Brompton Hospital, a tuberculous ulcer was found twice (Fenwick). In 2,501 gastric operations at the Mayo Clinic in four years only one instance was found. Broders, in a study of the literature (1917), accepts 49 proved cases, not one of which was primary. Ulcer is the most common lesion and occurred in about 80 per cent. of the cases. Miliary tubercles, pyloric stenosis and the occurrence of a nodule are the other lesions. Perforation of the stomach occurred in 6 of 12 cases collected by Marfan, thrice by a tuberculous gland. Three cases were described from the Hopkins clinic by Alice Hamilton (J. H. H. Bulletin, April, 1897).

(i) **Intestines.**—The tubercles may be (1) primary in the mucous membrane, or more commonly (2) secondary to disease of the lungs, or in rare cases the affection may (3) pass from the peritoneum.

(1) *Primary intestinal tuberculosis occurs most frequently in children*, in whom it may be associated with enlargement and caseation of the mesenteric glands, or with peritonitis. There is great discrepancy in the statistics on this point, and the question needs careful study. Biedert gives 16 cases in 3,104 instances of tuberculosis in children. In adults primary intestinal tuberculosis is rare, occurring in but 1 instance in 1,000 autopsies upon tuberculous adults at the Munich Pathological Institute; but now and then cases occur in which the disease sets in with irregular diarrhœa, moderate fever, and colicky pains. In a few cases hæmorrhage has been the initial symptom. Regarded at first as a chronic catarrh, it is not until emaciation becomes marked or signs of disease appear in the lungs that the true nature is apparent. Still more deceptive are the cases in which the tuberculosis begins in the *cæcum* and there are symptoms of appendicitis—tenderness in the right iliac fossa, constipation, or an irregular diarrhœa and fever. These signs may gradually disappear, to recur in a few weeks and still further complicate the diagnosis. Fatal hæmorrhage has occurred. Perforation into the peritoneum may take place, a pericæcal abscess may form, or in very rare instances there

is partial healing with great thickening of the walls and narrowing of the lumen. Tuberculosis of the *appendix* is found in about one per cent., but often can only be diagnosed microscopically. The symptoms are those of a suppurative appendicitis.

(2) *Secondary involvement* of the bowels is very common in chronic pulmonary tuberculosis, e. g., in 566 of the 1,000 Munich autopsies in tuberculosis. In only three of these cases were the lungs not involved. The *clinical* features are loss of appetite, nervous disturbances, such as depression, dyspepsia, abdominal pain more or less persistent, constipation if the small bowel and diarrhœa if the colon is involved. The patient may fail to gain or lose ground without evident cause. The lesions are chiefly in the ileum, cæcum, and colon. The caseation and necrosis lead to ulceration, which may be very extensive. In the ileum the Peyer's patches are chiefly involved and the ulcers may be ovoid, but in the jejunum and colon they are usually round or transverse to the long axis. The tuberculous *ulcer* has the following characters: (a) It is irregular, rarely ovoid or in the long axis, more frequently girdling the bowel; (b) the edges and base are infiltrated, often caseous; (c) the submucosa and muscularis are usually involved; and (d) on the serosa may be seen colonies of young tubercles or a well-marked tuberculous lymphangitis. Perforation and peritonitis are not uncommon in the secondary ulceration. Stenosis of the bowel from cicatrization may occur; the strictures may be multiple.

Localized chronic tuberculosis of the *ileo-cæcal region* is of great importance. The cæcum may present a chronic hyperplastic tuberculosis, which not uncommonly extends into the appendix and a definite tumor-like mass is formed in the right iliac fossa. This varies in size, is usually elongated in a vertical direction, hard, slightly movable, or bound down by adhesions and very sensitive to pressure. The tumor simulates more or less closely a neoplasm. The condition is characterized by gradual constriction of the lumen of the bowel, periodic attacks of severe pain, and alternating diarrhœa and constipation. The extremely localized character of the disease warrants an exploratory operation, as the results of enterectomy are favorable. Of 11 cases reported by F. M. Caird, 7 recovered. In a second form of this disease, occurring less frequently, there is no definite tumor mass, but a general induration and thickening in the right iliac fossa similar to the local changes produced by a recurring appendicitis. In this variety a fistula discharging fecal matter occasionally results. Both forms may be distinguished from the diseases they simulate by the finding of tubercle bacilli in the stools or in the discharge from the fistula when such exists.

Tuberculosis of the *rectum* has a special interest in connection with *fistula in ano*, which occurs in about 3.5 per cent. of cases of pulmonary disease. In many instances the lesion is tuberculous. It is very rarely primary, but if the tissue on removal contains bacilli and is infective the lungs are almost invariably involved. It is a common opinion that the pulmonary symptoms progress rapidly after the fistula is cut. This may have some basis if the operation consists in laying the tract open, and not in a free excision.

(3) *Extension from the peritoneum* may excite tuberculous disease in the bowels. The affection may be primary in the peritoneum or extend from the tubes in women or the mesenteric glands in children. The coils of intestines

become matted together, caseous and suppurating foci develop between the folds, and perforation may take place between the coils.

The *diagnosis* of intestinal tuberculosis should be made early, in which the general digestive disturbances, especially anorexia, are important. The X-ray study is of considerable aid. In *treatment*, the general measures, open air, careful diet, etc., are important. The use of light therapy, either by sunlight or artificial light from the quartz lamp, is often successful. X-ray exposures have helped some patients. Operation is indicated in cases in which the process is localized. Advanced disease of the lung or small bowel is a contra-indication.

VI. TUBERCULOSIS OF THE LIVER

This organ is very constantly involved in (a) *miliary tuberculosis*. This is seen in the general form, though the granules may be small and have to be looked for very carefully. In chronic tuberculosis miliary tubercles are not uncommon in the liver. (b) *Solitary tubercle*. Occasionally tuberculous masses are found, sometimes associated with perihepatitis, sometimes with tuberculous peritonitis, and in children with tuberculous adenitis. In a few cases the masses are large, though it is only in exceptional cases that the tumor can be felt through the abdominal wall. The organ may be enlarged by numerous caseous masses and present the clinical picture of an enlarged rough tender liver with jaundice, as in a case reported by Thayer. The solitary tubercles may be infected with pus organisms, soften and form an abscess. (c) *Tuberculosis of the bile ducts*. This is the most characteristic tuberculous change in the organ, and is not uncommon. It was well described by Bristowe in 1858. The liver is enlarged, and section shows numerous small cavities, which look at first like multiple abscesses in suppurative pylephlebitis, but the pus is bile-stained and the whole process is a local tuberculous cholangitis. (d) *Tuberculous cirrhosis*. With the eruption of miliary tubercles there may be slight increase in the connective tissue, which is overshadowed by the fatty change. In all the chronic forms of tubercle in this organ there may be fibrous overgrowth. Hanot, who described several varieties, states that the condition may be primary. Practically it is very rare, except in connection with chronic tuberculous peritonitis and perihepatitis, when the organ may be much deformed by a sclerosis involving the portal canals and the capsule, which may be involved in a polyserositis.

Jaundice is not common. It is usually due to some form of tuberculosis of the liver, either solitary tubercles or larger nodules. It is important to note its frequency in acute general miliary tuberculosis.

VII. TUBERCULOSIS OF THE BRAIN AND CORD

Tuberculosis of the brain occurs as (a) an *acute miliary infection causing meningitis and acute hydrocephalus*; (b) as a *chronic meningo-encephalitis*, usually localized, and containing small nodular tubercles; and (c) as the so-called solitary tubercle. Between the last two forms there are all gradations, and it is rare to see the meninges uninvolved. The acute variety has already been considered. The *chronic* form, which comes on slowly and

has the clinical characters of a tumor, is more common in the young. Of 148 cases collected by Pribram 118 were under fifteen years of age. Other organs are usually involved, particularly the lungs, the bronchial glands, or the bones. In rare instances no tubercles are found elsewhere. They occur most frequently in the cerebellum; next in the cerebrum, and then in the pons. The growths are often multiple, in 100 out of 183 cases (Gowers). They range in size from a pea to a walnut; large tumors occasionally occur, and sometimes an entire lobe of the cerebellum is affected. On section the tubercle presents a grayish-yellow, caseous appearance, usually firm and hard, and encircled by a translucent, softer tissue. The centre of the growth may be semi-diffuent. As in other localities the tubercle may calcify. The tumors are as a rule attached to the meninges, often to the pia at the bottom of a sulcus so that they look imbedded in the brain-substance. About the longitudinal fissure there may be an aggregation of the growths, with compression of the sinus, and the formation of a thrombus. The tuberculous tumor not infrequently excites acute meningitis. In localized meningo-encephalitis the pia is thickened, tubercles are adherent to the under surface and grow about the arteries. It is often combined with cerebral softening from interference with the circulation. Several of the most characteristic instances are on the meninges covering the insula. This form may occur in pulmonary tuberculosis, causing hemiplegia or aphasia which may persist for months.

In the *spinal cord* the same forms are found. The acute tuberculous meningitis is almost always cerebro-spinal. The solitary tubercle of the cord is rare and usually secondary. Herter reported 3 cases and collected 24 from the literature. The symptoms are those of spinal tumor or meningitis.

VIII. TUBERCULOSIS OF THE GENITO-URINARY SYSTEM

Any part of the genito-urinary system may be invaded. The disease may be limited for a long time to the urinary or to the genital tract. As a rule only in the later stages does involvement of both systems occur. The successive involvement of the organs may be so rapid that unless the case has been seen early it may be impossible to state with any degree of certainty which has been the primary seat of infection. There may be simultaneous involvement of various portions of the tract. In tuberculosis of the genito-urinary system one always has to bear in mind the possibility of latent disease elsewhere. As Bollinger says, tubercle bacilli may gain admission at some part of the respiratory tract without producing any lesion at the point of entrance, and finally reach a bronchial gland, where they set up a tuberculous process of extremely slow development without any symptoms. From this point bacilli may enter the blood stream, lodge in the epididymis, and produce nodules which are readily discovered. Such a case might be easily mistaken for one of primary genital tuberculosis, whereas the true primary tuberculous focus is far distant.

Infection of the genito-urinary tract occurs in various ways:

(a) **CONGENITAL.**—It has been met with in the fetus. The comparative frequency of tuberculosis of the testicle in very young children suggests very strongly that the uro-genital organs may be involved as a result of direct transmission of the disease.

(b) BY INFECTION FROM AREAS OF TUBERCULOSIS ALREADY EXISTING.—

(1) *Hæmatogenous*.—In many cases uro-genital tuberculosis is found at autopsy associated with disease of some distant organ, particularly the lungs, and it appears most probable that infection has been by the blood. Jani's observations, published by Weigert after the author's death, strongly support this theory. In sections of the organs of patients who died of pulmonary tuberculosis, he found tubercle bacilli in 5 out of 8 cases in the testicle, and in 4 out of 6 cases in the prostate, without microscopic evidences of tubercles in these organs. The bacilli lay, in the testis, partly within and partly close beside the cellular and granular contents of the seminal tubules, while in the prostate they were always situated in the neighborhood of the glandular epithelium.

(2) *Infection from the Peritoneum*.—This source of infection, in both men and women, is much more frequent than is commonly supposed. The intimate relationship between the peritoneum and bladder in both sexes, and with the vesiculæ seminales and vasa deferentia in the male, allows a ready way of invasion of these organs by direct extension. The peritoneum is a frequent source of genital tuberculosis in the female. No doubt many cases of tuberculosis of the Fallopian tubes originate from this source. The fact that the fimbriated extremity of the tube is often most seriously involved points in this direction, although this might be taken as a point in favor of blood infection, favored by its greater vascularity. Various observations go to show that the action of the cilia lining the lumina of the Fallopian tubes tends to attract particles introduced into the peritoneal cavity. Jani's observation showed the possibility of tubercle bacilli entering the tubes from the peritoneal cavity without there being any tuberculous peritonitis. He found typical tubercle bacilli in the lumen, in sections of a normal Fallopian tube, in a woman who died of pulmonary and intestinal tuberculosis. The explanation advanced was that the bacilli made their way through the thin peritoneal coat from one of the intestinal ulcers, thus reaching the peritoneal cavity, and thence were attracted into the Fallopian tube by the current produced by the action of the cilia. The tubes are affected in from 30 to 40 per cent. of cases of tuberculous peritonitis in females.

(3) *Infection by Direct Extension*.—The occurrence of direct extension from the peritoneum has been mentioned. In tuberculous ulceration of the intestine adhesions to the bladder or to the uterus and vagina in the female may occur, with resulting fistulæ and a direct extension of the disease. Perirectal tuberculous abscesses may lead to secondary involvement of some portion of the genito-urinary tract. Tuberculosis of the vertebræ may be followed by tuberculosis of the kidney as a result of direct extension.

(c) BY INFECTION FROM WITHOUT.—Whether uro-genital tuberculosis may occur as a result of the entrance of tubercle bacilli into the urethra or vagina is a disputed question. That bacilli gain admission to these passages during coitus with a person the subject of uro-genital tuberculosis, or by the use of foul instruments, seems quite probable. The possibility of genital tuberculosis occurring in the female as a result of coitus with a male the subject of tuberculosis in some portion of the genito-urinary system was first suggested by Cohnheim, who stated, however, that it rarely, if ever, occurred. In a patient with intestinal tuberculosis the tubercle bacilli might accidentally reach the urethra or vagina from the rectum.

Uro-genital tuberculosis is commonest between the ages of twenty and forty years—that is, during the period of greatest sexual activity. Males are affected much more frequently than females, the proportion being 3 to 1. This great difference is no doubt partly due to the more intimate relationship between the urinary and genital systems in the former than in the latter.

Once the uro-genital tract has been invaded the disease is likely to spread rapidly, and the method of extension is an important one. Frequently there is direct extension, as when the bladder is involved secondarily to the kidney by passage of the disease along the ureter, or where the tuberculous process extends along the vas deferens to the vesiculæ seminales. No doubt surface inoculation occurs in some instances, and to this cause may be attributed a certain percentage of cases of vesical and prostatic disease following tuberculosis of the kidney. Although this probability is acknowledged, there is doubt as to the possibility of the kidney becoming affected secondarily to the bladder or prostate by the direct passage of the bacilli up the lumen of one ureter; for in such a case we have to suppose that a non-motile bacillus ascends against an almost constant current of urine flowing in the opposite direction. The lymphatics may afford a means for the spreading of the disease, but in the majority of cases the infection is hæmatogenous. Cystoscopic examinations of the bladder not infrequently show the presence of tubercles beneath the mucous membrane before there is any evidence of superficial ulceration—a fact suggesting strongly a blood infection.

The discovery of tubercle bacilli in the urine or semen and the obtaining of tuberculous lesions in animals as a result of inoculation with the urinary sediment afford the only positive evidence of genito-urinary tuberculosis. Tubercle bacilli have been found in the semen of men with tuberculosis of the testicle or vesiculæ seminales. As the smegma bacillus has the same staining reaction as the tubercle bacillus, and, morphologically is practically indistinguishable from it, the greatest care must be used in obtaining the specimen of urine for examination, to eliminate all chances of contamination. One or more guinea-pigs should be inoculated with the suspected urine. If tubercle bacilli be present the animals will manifest tuberculous lesions in from three to five weeks.

Kidneys.—In general tuberculosis the kidneys frequently present scattered miliary tubercles. In pulmonary tuberculosis it is common to find a few nodules in the substance of the organ, or there may be pyelitis. In the first 17,000 admissions to the medical wards of the Johns Hopkins Hospital there were 1,085 cases of tuberculous infection. In 17 of these a clinical diagnosis of renal tuberculosis was made. Walker analyzed the first 1,369 autopsies in the same hospital and found that 784 had tuberculosis in some part of the body. In all there were 61 cases of renal tuberculosis. Of 482 cases of pulmonary tuberculosis showing symptoms during life, one or both kidneys were involved in 23. There were 36 cases of acute general miliary tuberculosis, and in every instance the kidney was affected. The 2 other cases of renal tuberculosis occurred in patients with latent disease. Primary tuberculosis of the kidneys is rare, and in no instance in the above series did Walker demonstrate a primary infection in the kidney. In a majority of the cases the process involves the pelvis and the ureter as well, sometimes the bladder and prostate. It may be difficult to say in advanced cases whether the disease has

started in the bladder, prostate, or vesicles, or whether it started in the kidneys and proceeded downward. Walker thinks that a hæmatogenous infection takes place in 90 per cent. of the cases, and that this is the channel of infection in the majority of instances where renal follows vesical tuberculosis rather than along the ureter. One kidney alone may be involved, and the disease creeps down the ureter and may only extend a few millimetres on the vesical mucosa. A man with aortic insufficiency, who had no lesions in the lungs, presented a localized patch in the pelvis of the kidney, involving a pyramid, while the ureter, 5 cm. from the bladder and at its orifice, was thickened and tuberculous. The prostate showed an area of caseation. The process is most common between twenty and thirty years of age, but it may occur at the extremes of age. In a series of 386 cases collected by Walker in which the sex was stated 182 of the patients were males and 204 females. In the earliest stage, which may be met with accidentally, the disease is seen to begin in the pyramids and calyces. Necrosis and caseation proceed rapidly, and the colonies of tubercles start throughout the pyramids and extend upon the mucous membrane of the pelvis. As a rule, from the outset it is a tuberculous pyo-nephrosis. It may be confined to one kidney, or progress more extensively in one than in the other. At autopsy both organs are usually found enlarged. In only 3 of the 61 autopsies previously referred to was the disease unilateral. One kidney may be completely destroyed and converted into a series of cysts containing cheesy substance. In the putty-like contents of these cysts lime salts may be deposited. In other instances the walls of the pelvis are thickened and cheesy, the pyramids eroded, and caseous nodules are scattered through the organ, even to the capsule, which may be thickened and adherent. The other organ is usually less affected, and shows only pyelitis or a superficial necrosis of one or two pyramids. The ureters are usually thickened and the mucous membrane ulcerated and caseous. Involvement of the bladder, vesiculæ seminales, and testes is not uncommon in males.

The SYMPTOMS are those of pyelitis. The urine may be purulent for years, and there may be little or no distress. Pain occurs in a number at an early stage but is more common later. Urination may be painful. Even before the bladder becomes involved micturition is frequent, and many instances are mistaken for cystitis. The frequent micturition is in part due to an initial polyuria, in part to reflex irritation, but chiefly to a non-tuberculous inflammation over the trigone of the bladder. It is usually the earliest and most constant symptom. Hæmaturia, of a mild grade, occurs at some time in the majority of cases. Dull, aching pain in the lumbar region is frequently complained of and may be the first symptom. The condition is for many years compatible with fair health. The curability is shown by the accidental discovery of a kidney, converted into cysts containing a putty-like substance. In cases in which the disease becomes advanced and both organs are affected constitutional symptoms are more marked. There is irregular fever, with chills and loss of weight and strength. General tuberculosis is common and the lungs are usually involved. In a case at the Montreal General Hospital a cyst perforated and caused fatal peritonitis.

Examination may detect tenderness on one side, or the kidney may be palpable in front on deep pressure, but tuberculous pyelo-nephritis seldom causes a large tumor. Occasionally the pelvis becomes enormously distended;

but this is rare in comparison with its frequency in calculous pyelitis. The urine shows pus cells, epithelium, often red blood cells and occasionally definite caseous masses. It is nearly always acid. Albumin is present but casts are rare. Tubercle bacilli may be demonstrated and should be searched for when there are any unusual sensations. There may be "showers" of bacilli at these times. The renal function is sometimes diminished.

DIAGNOSIS.—To distinguish the condition from calculous pyelitis is often difficult. Hæmorrhage may be present in both, though not nearly so frequently in the tuberculous disease. The appearance of the ureteral orifices on cystoscopic examination is often characteristic. The diagnosis rests on: (1) The detection of some focus of tuberculosis, as in the testis; (2) the presence of tubercle bacilli in the sediment; (3) the use of tuberculin; and (4) cystoscopic examination and catheterization of the ureters. Pyelography may aid by showing an irregular outline.

TREATMENT.—With only one kidney involved, immediate removal is indicated. If there is marked pulmonary disease or extensive involvement elsewhere, the decision is difficult but disease of the bladder often improves after removal of a tuberculous kidney. The usual general treatment should be given and tuberculin is sometimes very useful.

Tuberculosis of the adrenal glands is considered under Addison's Disease.

Ureter and Bladder.—This rarely occurs as a primary affection, but is nearly always secondary to involvement of other parts, particularly the kidney. Protracted cystitis which has come on without apparent cause is always suggestive of tuberculosis. The renal regions, the testes, the seminal vesicles, and the prostate should be examined with care. It may follow a pyelo-nephritis or be associated with primary disease of the prostate or vesiculæ seminales. Primary tuberculosis of the posterior wall of the bladder may simulate stone.

Prostate and Vesiculæ seminales.—The prostate is frequently involved in tuberculosis of the uro-genital tract. Barney collected a series of 1,862 cases of genito-urinary tuberculosis, the majority of the genital tract alone. Of 821 cases the epididymis showed tuberculosis in 617 (75 per cent.); of 1,675 cases the prostate and vesicles were involved in 1,169 (70 per cent.); disease of the testicle was found in 58 per cent. of 739 cases. The prostatic lobes contain nodules varying in size from a pea to a bean. There is great irritability of the bladder, and agonizing pain in catheterization. The seminal vesicles may be involved primarily or secondarily. They become thickened, enlarged and tender, sometimes nodular, and tubercle bacilli may be found in the fluid expressed by massage. An extremely rare lesion is primary urethral tuberculosis, which may simulate stricture. Pelouze has drawn attention to lympho-cystic urethral lesions as suggestive of active systemic tuberculosis. Chronic hyperplastic tuberculosis of the corpus cavernosum of the penis has been described.

Testes and Epididymes.—This may be primary but, more frequently, is secondary to tuberculous disease elsewhere. Many cases occur before the second year, and it is stated to have been met with in the fetus. In infants it is serious and usually associated with tuberculous disease in other parts. In 20 cases reported by Jullien, 6 were under one year, and 6 between one and two years old. In 5 of the cases both testicles were affected. Koplik holds that most of the instances of this kind are congenital, in Baumgarten's sense.

In young children the testis proper may be involved first, but in adults the globus major of the epididymis is first affected. Trauma and previous inflammation are predisposing factors. Extension to the testicle and other parts of the genital tract occurs later. The initial symptoms may be acute, resembling an acute epididymitis, followed by a chronic condition. More often the onset is insidious and the painless enlargement is found. Pain may occur later, frequently dull with sharp paroxysms. The cord may be thickened. Sexual desire may be unchanged but azoospermia is frequent. The semen may contain tubercle bacilli.

Tubercle of the testes is most likely to be confounded with syphilis. In the latter the body of the organ is most often affected, there is less pain, and the outlines of the growth are more nodular and irregular. In obscure peritoneal disease the detection of tubercle in a testis has not infrequently led to a correct diagnosis. The association of the two conditions is not uncommon. The lesion in the testis may heal completely or the disease may become generalized. Death from tuberculous meningitis is more common than in tuberculous lesions elsewhere. General infection has followed operation. Too much stress can not be laid on the importance of a routine examination of the testes.

Fallopian Tubes, Ovaries, and Uterus.—The fallopian tubes are a frequent seat of genital tuberculosis. The disease may be primary and produce a characteristic form of salpingitis, in which the tubes are enlarged, the walls thickened and infiltrated, and the contents cheesy. Adhesion takes place between the fimbriæ and the ovaries, or the uterus may be invaded. The condition is usually bilateral. It may occur in young children. Although, as a rule, evident to the naked eye, there are specimens resembling ordinary salpingitis, which show on microscopic examination numerous miliary tubercles (Welch and Williams). Tuberculous salpingitis may cause serious local disease with abscess formation, and may be the starting-point of peritonitis. Tuberculosis of the ovary is always secondary. There may be an eruption of tubercles over the surface in an extensive involvement of the stroma with abscess formation. Tuberculosis of the uterus is very rare. Only four examples have come under our observation, all in connection with pulmonary tuberculosis. It may be primary. The mucosa of the fundus is thickened and caseous, and tubercles may be seen in the muscular tissue. Occasionally the process extends to the vagina. Tuberculosis of the placenta is more common than has been supposed. Of 20 placentas from tuberculous women, 9 were affected; 5 of these were from cases of advanced disease of the lung. The lesions are easily overlooked.

IX. TUBERCULOSIS OF THE MAMMARY GLAND

There may be solitary or disseminated nodules, a sclerosing mastitis or caseation with abscess formation. The disease is most common between the fortieth and sixtieth years. The breast is frequently fistulous, unevenly indurated, and the nipple is retracted. The fistulæ and ulcers present a characteristic tuberculous aspect. There is also a cold tuberculous abscess of the breast. The axillary glands are affected in about two-thirds of the cases. The disease runs a chronic course of months or years. The diagnosis can be made

by the general appearance of the fistulæ and ulcers, and by the existence of tubercle bacilli. The prognosis is not serious, if total eradication of the disease be possible.

In 1836 Bedor described *hypertrophy* of the breast in the subjects of pulmonary tuberculosis. As a rule, if one gland is involved, usually on the side of the affected lung, the condition is one of chronic interstitial mammitis and is not tuberculous.

X. TUBERCULOSIS OF THE CIRCULATORY SYSTEM

Myocardium.—Miliary tubercles are sometimes met with in the acute disease. Larger caseous tubercles are excessively rare. There is also a sclerotic tuberculous myocarditis. The infection may pass from a mediastinal gland.

Endocardium.—In 216 autopsies in cases of chronic tuberculosis endocarditis was found in 12. It was present in only 151 among more than 11,000 autopsies on tuberculous cases (G. W. Norris). As a rule, it is a secondary form, the result of a mixed infection, so common in pulmonary tuberculosis. A true tuberculous endocarditis does, however, occur and as a rule, it is a vegetative form. In rare cases caseous tubercles develop.

Arteries.—Primary tuberculosis of the larger blood-vessels is very rare and is usually the result of invasion from without. The disease may, however, occur in a large artery and not result from external invasion. Adams (1929) found 36 cases of tuberculosis of the aorta, in 20 of which, including his case, the aorta was involved from without by extension of a tuberculous process. Aneurism may form and rupture. In the lungs and other organs attacked by tuberculosis the *arteries* are involved in an acute infiltration which usually leads to thrombosis, or tubercles may develop in the walls and proceed to caseation and softening, frequently with a resulting hæmorrhage. By extension into vessels, particularly veins, the bacilli are widely distributed with the production of miliary tuberculosis.

XI. THE PROGNOSIS IN TUBERCULOSIS

The parable of the sower already referred to expresses better than in any other way the question of individual predisposition. There are five groups of cases of tuberculous infection. 1. Those who become infected and recover spontaneously without knowing they have been infected. 2. Mild infections which produce slight symptoms, recovery following after a few months of change of air or special treatment. 3. Cases with well-marked signs of lung disease in which thorough treatment is followed by complete recovery. 4. Cases with extensive local disease and cavity formation in which arrest takes place and the patients live for many years. 5. The cases in which the infection is of such a type that death follows no matter what is done. The late Austin Flint, *facile princeps* among American students of the disease, called attention to the self-limitation and intrinsic tendency to recovery in pulmonary tuberculosis. This natural tendency to cure is still more strikingly shown in lymphatic and bone tuberculosis.

The following may be considered favorable circumstances in the prognosis of pulmonary tuberculosis: An early diagnosis, a good family history, previous

good health, a strong digestion, a suitable environment, and an insidious onset, without high fever, and without extensive pneumonic consolidation. Cases beginning with pleurisy seem to run a more protracted and more favorable course. Repeated attacks of hæmoptysis are unfavorable. When well established the course of tuberculosis in any organ is marked by intervals of weeks or months in which the fever lessens, the symptoms subside, and there is improvement in the general health.

In pulmonary cases the duration is extremely variable. Much depends on the condition when the diagnosis is made and the possibilities for prolonged and thorough treatment. Pollock's statistics of over 3,500 cases show a mean duration of the disease of over two years and a half. Williams's analysis of 1,000 cases in private practice shows a much more protracted course, as the average duration was over seven years.

Tuberculosis and Marriage.—Under the subject of prognosis comes the question of the marriage of persons who have had tuberculosis, or in whose family the disease prevails. The following brief statements may be made:

(a) Subjects with healed lymphatic or bone tuberculosis marry with personal impunity and may beget healthy children. In such families adenitis, caries of the bone, arthritis, cerebral and pulmonary tuberculosis are more common. The risks, however, are such as may properly be taken.

(b) The question of marriage of a person who has arrested or cured lung tuberculosis is more difficult to decide. In a male the personal risk is not so great; and when the health and strength are good, the external environment favorable, and the family history not extremely bad, the experiment—for it is such—is often successful, and many healthy and happy families are begotten under these circumstances. In women the question is complicated with that of child-bearing, which increases the risks enormously. With a localized lesion, absence of hereditary taint, good physique, and favorable environment marriage might be permitted. When tuberculosis has existed in a girl whose family history is bad, and whose physique is below the standard, the physician should, if possible, place his veto upon marriage.

(c) With existing disease, fever, bacilli, etc., marriage should be prohibited. Pregnancy usually hastens the process, though it may be held in abeyance. After parturition the disease advances rapidly. There is much truth, indeed, in the remark of Dubois: "If a woman threatened with phthisis marries, she may bear the first accouchement well; a second, with difficulty; a third, never." Conception may occur in an advanced stage of the disease.

XII. PROPHYLAXIS IN TUBERCULOSIS

General.—Among the more important measures may be mentioned the following: *First*, education of the public. Much has been done in this direction by the antituberculosis crusade, which has resulted in the formation of many active societies, and has stimulated widespread interest in the disease. *Secondly*, the placing of pulmonary tuberculosis on the list of reportable diseases. This gives the board of health control of the situation, and is a most helpful measure. *Thirdly*, improved conditions of living, particularly as regards food and housing. *Fourthly*, direct preventive measures, such as the enactment of laws against spitting in public, the proper disinfection and

cleaning of the rooms which have been occupied by tuberculous patients, the inspection of cattle and pasteurization of milk. *Fifthly*, in the large cities, organization of sanatoria and hospitals for early curable and late incurable cases, and the establishment of separate dispensaries with a system of visiting the patients at their homes by specially assigned nurses. *Lastly*, the care of the sputum of the tuberculous. Thorough boiling or putting it into the fire is sufficient. In hospitals it is well to have printed directions as to the care of the sputum, and also printed cards for out-patients, giving the most important rules. It should be explained to the patient that the only risk, practically, is from this source.

Individual.—Individual prophylaxis in the case of delicate children is most important. An infant born of tuberculous parents, or of a family in which tuberculosis prevails, should be brought up with the greatest care and guarded most particularly against infections of all kinds. Special attention should be given to the throat and nose, and on the first indication of mouth-breathing, or any obstruction of the naso-pharynx, a careful examination should be made for adenoid vegetations. The child should be clad in flannel and live in the open air as much as possible, avoiding close rooms. It is a good practice to sponge the throat and chest night and morning with cold water. Special attention should be paid to diet and to the mode of feeding. The meals should be at regular hours and the food plain and substantial. From the outset the child should be encouraged to drink freely of milk. As the child grows older, systematically regulated exercise or a course of pulmonary gymnastics may be taken. In the choice of an occupation preference should be given to an out-of-door life. Immunization of infants by the use of *Bacillus Calmette-Guérin* (B-C-G) is under trial and final judgment can not be passed. If efficient, it or some other such method, would be indicated in children born of parents with open pulmonary tuberculosis.

The examination of children who have been in contact with tuberculous individuals is important. Four groups of suspects come to tuberculosis dispensaries: (1) The under-fed, anæmic, badly developed child, without local lesions; the question is one of malnutrition. (2) Cases of thymo-lymphatism usually having adenoids and enlarged tonsils. These children may not be anæmic, but they have stunted, badly formed chests, and the superficial lymph glands may be enlarged. (3) Children with obviously enlarged lymph glands, usually cervical; it may not be easy to determine whether the adenopathy is due to throat infection or bad teeth, or whether it is tuberculous. (4) Children with signs in the chest pointing to a definite local lesion, the tuberculous nature of which may not at first be easy to determine.

The trifling ailments of children should be carefully watched. In the convalescence from the fevers the greatest caution should be exercised to prevent catching cold. An open air life, a generous diet, especially in fats, and iron or arsenic if there is anæmia, are important aids. Care of the throat is important; enlarged tonsils and adenoids should be removed.

The patient should cover the mouth in coughing and be instructed as to the care of the sputum. To ensure the latter is one of the most important points in prevention. The dishes used by a patient with bacilli in the sputum should be boiled and those used by others should not be washed in the same water or dried with the same cloth as those used by the patient.

XIII. TREATMENT OF TUBERCULOSIS

The Natural or Spontaneous Cure.—The spontaneous healing of local tuberculosis is an every-day affair. A majority of those infected never have the disease, i.e., they recover without symptoms, without the slight lesion having disturbed the health. Many cases of adenitis and disease of the bone or of the joints terminate favorably. The healing of pulmonary tuberculosis is shown clinically by the recovery of patients in whose sputum elastic tissue and bacilli have been found; anatomically, by the presence of lesions in all stages of repair. In the granulation products and associated pneumonia a scar-tissue is formed, while the smaller caseous areas become impregnated with lime salts. To such conditions alone should the term healing be applied. When the fibroid change encapsulates but does not involve the entire tuberculous tissue, the tubercle may be termed involuted or quiescent, but is not destroyed. When cavities of any size have formed, healing, in the proper sense of the term, does not occur. We have yet to see a specimen which would indicate that a vomica had cicatrized. Cavities may be greatly reduced in size—indeed, an entire series of them may be so contracted by sclerosis of the tissue about them that an upper lobe, in which this process most frequently occurs, may be reduced to a third of its ordinary dimensions. Laennec understood thoroughly this natural process of cure and recognized the frequency with which old tuberculous lesions occurred in the lungs. He described *cicatrices complètes* and *cicatrices fistuleuses*, the latter being the shrunk cavities communicating with the bronchi; and remarked that as tubercles in the glands often heal, why should not the same take place in the lungs?

There is an old German axiom, *Jedermann hat am Ende ein bisschen Tuberculose*, a statement partly borne out by the statistics showing the proportion of persons dying of all disease in whom quiescent or tuberculous lesions are found in the lungs. We find at the apices the following conditions, which have been held to signify healed tuberculous processes: (a) Thickening of the pleura, usually at the posterior surface of the apex, with subadjacent induration for a short distance. This has, perhaps, no greater significance than a milky patch on the pericardium. (b) Puckered cicatrices at the apex, depressing the pleura, and on section showing a pigmented, fibrous scar. The bronchioles in the neighborhood may be dilated, but there are neither tubercles nor cheesy masses. This may sometimes, but not always, indicate a healed tuberculous lesion. (c) Puckered cicatrices with cheesy or cretaceous nodules, and with scattered tubercles in the vicinity. (d) The *cicatrices fistuleuses* of Laennec, in which the fibrosis has reduced the size of one or more cavities which communicate directly with the bronchi.

General Measures.—The cure of tuberculosis is a question of nutrition; digestion and assimilation control the situation; as a rule, make a patient grow fat and strong, and the local disease may be left to take care of itself. There are three indications: First, to place the patient in surroundings most favorable for the maintenance of a maximum degree of nutrition; second, to take such measures as, in a local or general way, influence the tuberculous processes; third, to alleviate symptoms. The importance of rest must always be kept in mind and the amount of exertion allowed carefully ordered.

OPEN-AIR TREATMENT.—The value of fresh air and out-of-door life is well

illustrated by an experiment of Trudeau. Inoculated rabbits confined in a dark, damp place rapidly succumbed, while others, allowed to run wild, either recovered or showed slight lesions. It is the same in human tuberculosis. A patient confined to the house—particularly in the close, stuffy dwellings of the poor—is in a position analogous to that of the rabbit confined in the cellar; whereas a patient living in the fresh air or sunshine for the greater part of the day has chances comparable to those of the rabbit running wild.

The open-air treatment of tuberculosis may be carried out at home, by change of residence to a suitable climate, or in a sanatorium.

(a) *At Home*.—In a majority of all cases the patient has to be cared for in his own home, and, if in the city, under very disadvantageous circumstances. Much, however, may be done even in cities to promote arrest by insisting upon systematic treatment. How much can be done by care and instruction is shown by the success of J. H. Pratt's *tuberculosis classes*. As not 5 per cent. of the patients can be dealt with in sanatoria, it is surprising and gratifying to see how successful the home treatment may be. Even in cities the patients may sleep out of doors, and the results obtained by Pratt, Millett, and others are as good as any that have been published. While there is fever the patient should be at rest in bed, and night and day the windows should be open, so that he may be exposed freely to the fresh air. Low temperature is not a contra-indication. If there is a balcony or a suitable yard or garden, on the brighter days the patient may be wrapped up and put in a reclining chair or on a sofa. The important thing to emphasize is the fact that neither cough, fever, night sweats, and not even hæmoptysis contra-indicate a full exposure to fresh air. In country places this can be carried out much more effectively. In the summer the patient should be out of doors for at least eleven or twelve hours, and in winter six or eight hours. At night the room should be cool and thoroughly well ventilated. It may require several months of rest treatment in the open air before the temperature falls to normal.

(b) *Treatment in Sanatoria*.—Perhaps the most important advance in the treatment of tuberculosis has been in the establishment of institutions in which patients live according to strict rules. To Brehmer, of Göbersdorf, we owe the successful execution of this plan, which has been followed with most gratifying results. In the United States the zeal, energy, and scientific devotion of Edward L. Trudeau demonstrated its feasibility, and the Saranac institution is a model of its kind. The results at hundreds of institutions demonstrate the great importance of system and rigid discipline in carrying out a successful treatment. Much has been done to promote the sanatorium treatment and the good results have quite justified the heavy expenditure of money. In many places it has been demonstrated that with an inexpensive plant excellent results may be obtained. A reaction has naturally followed the "stuffing" plan of feeding, and more reasonable methods are now employed. The "absolute rest" plan has been modified to meet individual cases. The all-important matter is the establishment near to the larger cities of public sanatoria for treatment in the early stages. The large general hospitals should have special out-patient departments for tuberculous patients, from which suitable cases could be sent to the sanatoria. Much discussion has taken place as to the result of sanatorium treatment. There is no doubt of its extraordinary benefits in suitable cases. To pay a visit with Dr. Bardwell to the King

Edward Sanatorium at Midhurst and see nearly every one of 100 patients looking in good condition with fresh air, judicious rest, proper exercise and diet, without drugs and without tuberculin, impresses one immensely with the value of the method. Statistics are notoriously uncertain, but there is perhaps no institution in which greater care has been taken to trace the after-history of the patients than at the Adirondack Sanatorium. The total number of patients from the years 1885 to 1921 inclusive was 5,395. It has been impossible to trace 334 of these. Of the remaining 5,061, 2,997 were living (1921) and 2,064 dead.

(c) *Climatic Treatment*.—This, after all, is only a modification of the open-air method. The first question to be decided is whether the patient is fit to be sent from home. In many instances it is a positive hardship. A patient with well-marked cavities, fever, night sweats, and emaciation is much better at home, and the physician should not be too much influenced by the importunities of the sick man or his friends. The requirements of a suitable climate are a pure atmosphere, an equable temperature not subject to rapid variations, and a maximum amount of sunshine. Given these three factors, it makes little difference where a patient goes, so long as he lives an outdoor life. The different climates may be grouped into the high altitudes, the dry, warm climates, and the moist, warm climates. Among high altitudes in the United States, the Colorado, Arizona and New Mexico resorts are the most important. The rarefaction of the air in high altitudes is of benefit in increasing the respiratory movements, but brings about in time dilatation of the air-vesicles and a permanent increase in the size of the chest which is a disadvantage when such persons attempt subsequently to reside at the sea-level. The great advantage of these western resorts is that they are in progressive, prosperous countries, in which a man may find means of livelihood. In Europe the chief resorts at high altitudes are Davos, Les Avants, and St. Moritz. Of resorts at a moderate altitude, Asheville and the Adirondacks are the best known in America. The Adirondack cure has become quite famous. One decided advantage is that after arrest of the disease the patient can return to the sea-level without any special risk. The cases most suitable for high altitudes are those in which the disease is limited, without much cavity formation, and without much emaciation. The thin, irritable patients with chronic tuberculosis and a good deal of emphysema are better at the sea-level. The cold winter climate seems to be of decided advantage in tuberculosis, and in the Adirondacks, where the temperature falls sometimes to 20° or even more below zero, the patients are able to lead an out-of-door life throughout the entire winter.

Of the moist, warm climates, in America Florida and the Bermudas, in Europe the Madeira Islands, and in Great Britain Eastbourne, Bournemouth, Torquay, and Falmouth are the best known. Of the dry, warm climates, Southern California in the United States is the most satisfactory. Many of the health resorts in the Southern States are delightful winter climates for tuberculous cases. Egypt, Algiers, and the Riviera are the most satisfactory resorts for patients from Europe.

Other considerations which should influence the choice of a locality are good accommodations and good food and, most important of all, a competent physician. Very much is said concerning the choice of locality in the different

stages of pulmonary tuberculosis, but when the disease is limited to an apex, in a man of fairly good personal and family history, the chances are that he may fight a winning battle if he lives out of doors in any climate, whether high, dry, and cold, or low, moist, and warm. With bilateral disease and cavity formation there is but little hope of permanent cure, and the mild or warm climates are preferable.

Heliotherapy.—Both natural and artificial heliotherapy is of great value in some forms of tuberculosis, especially of the bones, glands, intestines, and peritoneum. It has to be carefully supervised.

Measures which, by their Local or General Action, Influence the Tuberculous Process.—Under this heading we may consider the specific, the dietetic, and the general medicinal treatment of tuberculosis.

(a) **SPECIFIC TREATMENT.**—Introduced by Koch in 1890, the tuberculin treatment soon fell into disfavor, but, in spite of the bad results that followed its injudicious use, certain men (among them, particularly, Trudeau) continued to use it. Of late years there has been a reaction in its favor, and tuberculin is lauded by some as the one and only means of cure. In suitable cases it may have a beneficial influence; the difficulty is to decide which they are. In certain surgical forms of tuberculosis it has some usefulness but in the vast majority of cases of pulmonary tuberculosis it has no place. Tuberculin is a remedy potent for harm if improperly used and it should be given only to carefully selected cases by those experienced in its use. A variety of preparations come under the name tuberculin: O. T. and T. R., which are Koch's old and new preparations; Denys' tuberculin, *bouillon filtré*, known as B. F., and a bacillary emulsion of Koch, B. E. The initial dose should be so small that a reaction will not occur and 1/200,000 or 1/100,000 mgm. is to be preferred to the usual dose of 1/2,000 or 1/1,000 mgm. Re-inoculations are given at weekly intervals, the increase in dosage being so small that reactions do not result. It is contraindicated in patients with fever, hæmoptysis, and pleurisy or acute features of any kind. It is not desirable—quite the contrary in fact—to get a severe general reaction, particularly as this may be associated with marked focal reactions. The aim striven for is to get as high a grade of tuberculin tolerance as possible. It may require many months of the small dose, non-reaction method to accomplish this. Trudeau, who had probably the longest individual experience of anyone using tuberculin, began with doses so small that no reaction is produced; then the dose is cautiously raised, avoiding the slightest reaction. Treatment with tuberculin should not be begun unless it can be continued for some months.

(b) **DIETETIC TREATMENT.**—The outlook in tuberculosis depends much upon the digestion and it is rare to see recovery in a patient in whom there is persistent gastric trouble. Basal metabolism may be normal or slightly above normal. Excessive feeding may increase it and so exaggerate respiration. Probably 2,500 calories a day are enough with 60 grams of protein. The early nausea and loss of appetite in many cases are serious obstacles. Many patients loathe food of all kinds. A change of air may promptly restore the appetite. When this is impossible, and if, as is almost always the case, fever is present, the patient should be at rest, kept in the open air nearly all day, and fed at stated intervals with small quantities either of milk, buttermilk, or koumyss, alternating if necessary with meat juice and egg albumen. Some patients

who are disturbed by eggs and milk do well on koumyss. Raw eggs are suitable for some patients and may be taken between meals. The diet should be as varied as possible and care taken to give sufficient vitamins. Over-feeding should be guarded against, especially in toxic patients.

In many cases the digestion is not at all disturbed and the patient can take an ordinary diet. It is remarkable how rapidly the appetite and digestion improve with the fresh air treatment, even in patients in the city. Care should be taken that drugs do not disturb the stomach. Not infrequently the sweet syrups used in cough mixtures, cod-liver oil, and creosote produce irritation, and by interfering with digestion do more harm than good. On the other hand, the bitter tonics, with acids, and the various malt preparations are often satisfactory. A routine administration of alcohol is not advisable, and there is no evidence that its use promotes fibroid processes in the tuberculous areas. In the advanced stages, particularly when the temperature is low between eight and ten in the morning, whisky and milk, or whisky, egg, and milk may be given with advantage.

(c) **REST AND EXERCISE.**—One month in bed is a minimum period for all patients beginning treatment, whether febrile or afebrile. Fever is an indication for absolute rest. Greater emphasis is being placed on the importance of prolonged rest, meaning rest in bed. The duration of rest must be decided for each patient, and better too long than too short. Some employ a plan based upon the view that physical exercise induces auto-inoculation, the extent of which may be controlled by the amount of muscular effort. By a study of the fever chart, the body weight, the amount of sputum, and the appetite the rate of progress may be estimated. The febrile patient is regarded as one in whom auto-inoculation is excessive. To overcome this the patient is immobilized in bed so far as possible, and not allowed to make any movements whatever. The effect of this is often remarkable in reducing the fever. Once afebrile, the principal element in the treatment is the induction of an auto-inoculation by exercises, which some believe has much the same effect as a dose of tuberculin. A scheme of graded labor has many advantages in sanatorium life, and the results at some places are very gratifying.

(d) **IMMOBILIZING THE LUNG.**—Years ago Cayley induced *pneumothorax* in a case of hæmoptysis. The method did not come into general use; but later was advocated in pulmonary tuberculosis by Forlanini and J. B. Murphy. Filtered air is introduced into the pleural cavity. At first from 200 to 300 c. c.; later as much as 500 c. c. are introduced, so that the lung is completely collapsed, and there is a neutral or slightly positive interpleural pressure. It is used in patients with unilateral or predominately unilateral lesions who do not respond to the usual treatment. There are dangers, as hæmoptysis, serous effusion, pleural shock and empyema, and a serious objection is the duration of the treatment, as the collapse should be for long periods, years, not months, and the pleural cavity requires to be refilled every few weeks.

Other methods of immobilizing the lung include postural rest by having the patient lie on the affected side (Webb), controlled and slow diaphragmatic breathing (Knopf), fixation of the chest wall by strapping or apparatus, and thoracoplastic compression. The last is useful when pneumothorax has failed or is impossible; marked fibroid change and thickened pleura are favorable conditions for it. Phrenic evulsion is also used.

(e) **GENERAL MEDICAL TREATMENT.**—No drugs have any special or peculiar action upon tuberculous processes. The influence which they exert is upon the general nutrition, increasing the physiological resistance, and rendering the tissues less susceptible to invasion. The following are the most important remedies which seem to act in this manner:

Creosote may be administered in increasing doses, beginning with 1 minim three times a day and, if well borne, increasing the dose to 8 or 10 minims. It may also be given in solution with tincture of cardamon and alcohol. It is an old remedy, strongly recommended by Addison, and it has a positive value for some patients. It may be used as an inhalation. Guaiacol may be given as a substitute, either internally or hypodermically.

Cod-liver Oil.—In glandular and bone tuberculosis this remedy is undoubtedly beneficial in improving nutrition. In pulmonary tuberculosis its action is less certain, and it is scarcely worthy of the unbounded confidence which it enjoyed for so many years. It should be given in small doses, not more than a teaspoonful three times a day after meals. It seems to act better in children than in adults. Fever and gastric irritation are contra-indications to its use. Rich cream is an excellent substitute.

Arsenic.—There is no general tonic more satisfactory in cases of tuberculosis of all kinds than Fowler's solution. It may be given in 5-minim (0.3 c. c.) doses three times a day and gradually increased, stopping its use whenever unpleasant symptoms arise, and in any case intermitting it every third or fourth week. Intramuscular injections of the salts of cacodylic acid have been used to combat the anæmia with, it is claimed, unusual success.

Treatment of Special Symptoms.—(a) **THE FEVER.**—There is no more difficult problem than the treatment of the pyrexia of tuberculosis. The patient should be at absolute rest, and in the open air night and day for some weeks. Fever does not contra-indicate an out-of-door life, but it is well for patients with a temperature above 100.5° F. to be at rest. For the continuous pyrexia or the remittent type of the early stages, quinine and the salicylates may be tried; but they are uncertain and rarely reliable. It is better, when the fever rises above 103° F. to rely upon sponging. When softening has taken place and the fever assumes the characteristic septic type, the problem becomes still more difficult. As shown by Chart V, the pyrexia, at this stage, lasts only for twelve or fifteen hours. As a rule there are not more than from eight to ten hours in which the fever is high enough to demand antipyretic treatment. Sometimes phenacetine, given in 2-grain (0.13 gm.) doses every hour for three or four hours before the rise in temperature prevents entirely or limits the paroxysm. It answers better in this way than given in single doses. Careful sponging of the extremities for from half an hour to an hour during the height of the fever is useful.

(b) **SWEATING.**—Atropine, in doses of gr. $\frac{1}{120}$ – $\frac{1}{60}$ (0.0005–0.001 gm.), and aromatic sulphuric acid in large doses are the best remedies. When there are cough and nocturnal restlessness, morphia (gr. $\frac{1}{8}$, 0.008 gm.) may be given with the atropine. Camphoric acid (gr. x, 0.65 gm.) at bedtime may be tried. The patient should use light flannel garments, as cotton ones, when soaked with perspiration, have a very unpleasant feeling.

(c) **COUGH.**—The cough is a troublesome, though necessary, feature in

pulmonary tuberculosis. Unless very worrying and disturbing sleep at night or so severe as to produce vomiting, it is not well to attempt to restrict it. When irritative in character, inhalations are useful, particularly the tincture of benzoin or preparations of menthol, creosote, or turpentine. Some of the most irritable and distressing forms of cough result from laryngeal erosions. The nocturnal cough, which begins just as the patient gets into bed and is preparing to fall asleep, requires, as a rule, preparations of opium. Codeine (gr. $\frac{1}{4}$ - $\frac{1}{2}$, 0.016-0.03 gm.) may be given. An excellent combination is morphia (gr. $\frac{1}{8}$, 0.008 gm.), dilute hydrocyanic acid (℥ ii, 0.2 c. c.), and syrup of wild cherry (3 j, 4 c. c.). The spirit of chloroform, or a mixture of chloroform and sedatives or Hoffman's anodyne, given in whisky before going to sleep, is efficacious. Mild counter-irritation or the application of a hot poultice will sometimes promptly relieve the cough. The morning cough is often relieved by taking immediately after waking a glass of hot milk or a cup of hot water, to which 15 grains of bicarbonate of soda have been added. In the later stages, when cavities have formed, the accumulated secretion must be expectorated and the paroxysms of coughing are most exhausting. The sedatives, such as morphia and hydrocyanic acid, should be given cautiously. The aromatic spirit of ammonia may help to allay the paroxysm. When the expectoration is profuse, creosote internally, or inhalations of turpentine and iodine, or oil of eucalyptus, are useful. For the troublesome dysphagia a solution of cocaine (gr. x, 0.6 gm.) with boric acid (gr. v, 0.3 gm.) in glycerine and water (3 j, 30 c. c.) may be used locally.

(d) DIARRHŒA.—For this large doses of bismuth with Dover's powder, and small starch enemata, with or without opium, may be given. The acetate of lead and opium pill often acts promptly, and the acid diarrhœa mixture, dilute acetic acid (℥ x-xv, 1 c. c.), morphia (gr. $\frac{1}{8}$, 0.008 gm.), and acetate of lead (gr. j-ij, 0.1 gm.), may be tried. In some cases, 5 c. c. of a 5 per cent. solution of calcium chloride injected intravenously is useful.

(e) The treatment of the hæmoptysis will be considered in the section on hæmorrhage from the lungs. Dyspnœa is rarely a prominent symptom except in the advanced stages, when it may be very troublesome and distressing. Ammonia and morphia, cautiously administered, may be used.

If the pleuritic pains are severe, the side may be strapped, or painted with tincture of iodine. The dyspeptic symptoms require careful treatment, as the outlook in individual cases depends much upon the condition of the stomach. Small doses of calomel and soda often allay the distressing nausea.

The treatment of lesions such as of the kidney, epididymis, etc., is surgical if the condition is recognized early enough. Disease elsewhere, as in the lungs, is not a necessary contra-indication. The possible harm resulting from ether anæsthesia must always be kept in mind.

A last word on the subject of tuberculosis to the general practitioner. *The leadership of the battle against this scourge is in your hands. Much has been done, much remains to do. By early diagnosis and prompt, systematic treatment of individual cases, by striving in every possible way to improve the social condition of the poor, by joining actively in the work of the local and national antituberculosis societies you can help in the most important and the most hopeful campaign ever undertaken by the profession.*

XXII. TULARÆMIA

This is a specific infectious disease due to *Bacterium tularensis*, transmitted from rodents to man by insects (fly, lice, flea and bed-bug) or acquired in handling infected animals.

History.—In 1910, R. A. Pearse of Brigham City, Utah, reported cases of infection due to the bite of a fly and described the symptoms. McCoy and Chapin in 1912 discovered *Bacterium tularensis* as the cause of a disease in rodents resembling plague. The first human case with proved bacteriological findings was in Cincinnati in 1913 (Wherry and Lamb), the cultures being made from conjunctival ulcers. Subsequently the organism was obtained from patients in Utah. There have been a number of cases in laboratory workers contracted while working with the organism. The name tularæmia was suggested by Francis in 1921 (from Tulare county).

Etiology.—The disease in animals affects rabbits particularly but squirrels, rats and field mice also suffer from it. The blood-sucking fly *Chrysops discalis* is common in Utah, where the disease occurs. The rabbit louse, the bed-bug, the mouse louse, the squirrel flea, wood-tick, and the stable fly can transmit the disease from animal to animal. Several of them bite both man and rodents. Infected rodents have been found in Utah, Indiana and California. It is a disease widely distributed in the United States.

Symptoms.—The insect bite may not be noticed until about the third day when necrosis appears followed by a small ulcer which leaves a permanent scar. The related lymph-glands show rapid involvement and in a number of cases suppuration results. The occurrence of conjunctival ulcers has been mentioned. Other forms are the glandular (epitrochlear and axillary glands especially) without any evident primary lesion and “typhoid” without primary lesion or gland involvement. The general features are chills, fever of two or three weeks’ duration, which may be high and with daily remissions, marked prostration, a course of several weeks with weakness, often striking during convalescence. Various skin eruptions may occur. Peritonitis and ascites have occurred with the organism in the fluid. The death rate is low.

Diagnosis.—The local lesions are suggestive. The organism has been obtained from guinea-pigs inoculated from the patient’s blood or from the pus from the suppurating glands. Complement-fixation and agglutination tests are positive. As some patients show no glandular features and others very slight general disturbances mild cases are easily overlooked. The specific agglutinins do not appear until the second week but remain for many years. Some serums agglutinate *Brucella abortus* and *melitensis*.

Treatment.—Little can be said as to prevention; laboratory workers should exercise great care in handling the organisms. The treatment of an attack is that of an acute infection.

B. THE MYCOSES

The local and general infections caused by the group of fungoid organisms variously classed as Streptothrix, Actinomyces, Cladothrix and Leptothrix may be grouped under the term Mycoses. Four or five of these diseases are of sufficient importance to be considered in a work of this scope.

I. ACTINOMYCOSIS

Definition.—A chronic infective disorder produced by the actinomycetes or ray-fungus, *Actinomyces bovis*.

Etiology.—The disease is widespread among cattle, and occurs also in the pig. It was first described by Bollinger in the ox, in which it forms the affection known in America as “big-jaw.” The first accurate description of the disease in man was given by James Israel, and subsequently Ponfick insisted upon the identity of the disease in man and cattle.

In the United States and England the disease is less common than in Germany. It is nearly three times as common in men as in women.

The parasite in both man and cattle can be seen in the pus from the affected region as yellowish or opaque granules from one-half to two millimetres in diameter, which are made up of cocci and radiating threads, presenting bulbous, club-like terminations. The youngest granules are gray in color and semi-translucent; in these the bulbous extremities are wanting. The parasite has been successfully cultivated, and in a few instances the disease has been inoculated both with the natural and artificially grown organism.

Mode of Infection.—There is no evidence of direct infection with the flesh or milk of diseased animals. The streptothrix has not been detected outside the body. It seems highly probable that it is taken in with the food. The site of infection in a majority of cases in man and animals is in the mouth or neighboring passages. In the cow, possibly also in man, barley, oats, and rye have been carriers of the germ.

Morbid Anatomy.—As in tubercle, the first effect is the destruction of adjacent cells and the attraction of leucocytes—later the surrounding cells begin to proliferate. After the tumor reaches a certain size there is great proliferation of the surrounding connective tissue, and the growth may, particularly in the jaw, look like, and was long mistaken for, osteosarcoma. Finally suppuration occurs, which in man, according to Israel, may be produced directly by the actinomycetes itself.

Clinical Forms.—(a) DIGESTIVE TRACT.—The fungus has been found in the cavities of carious teeth. The jaw has been affected in a number of cases in man. There is swelling of one side of the face, or a chronic enlargement of the jaw which may simulate sarcoma. The tongue may be involved, showing small indolent growths either primary or following disease of the jaw. The salivary glands have been affected. In the intestines the disease may occur as a primary or secondary affection. The most common seat is the region of the cæcum and appendix. With involvement of the appendix the process tends to be chronic without marked acute features. There is a mass which increases in size and gradually becomes fixed by spreading induration with marked adhesions. There may be extension to the bones and pelvic organs and metastases to the liver and lungs. Primary actinomycosis of the large intestine with metastases has also been found and Ransom found the actinomycetes in the stools. Actinomycotic peritonitis due to infection through a gastrostomy wound has been described. Actinomycosis of the liver is rare. Auvray in 1903 could only collect 31 cases (Rolleston). It forms a most characteristic lesion, an alveolar honey-combed abscess—like a sponge soaked in

pus. It is usually secondary to an intestinal lesion, but in a few cases no other focus was found.

(b) **PULMONARY ACTINOMYCOSIS.**—In 1878 Israel described a remarkable mycotic disease of the lungs, which subsequent observation showed to be the affection described the year before by Bollinger in cattle. It is a chronic disorder, characterized by cough, fever, wasting, and a muco-purulent, sometimes fetid, expectoration. The lesions are unilateral in a majority of the cases. Hodenpyl classifies them in three groups: (1) Lesions of chronic bronchitis; the diagnosis has been made by the presence of the actinomycetes in the sputum. (2) Miliary actinomycosis, closely resembling miliary tubercle, but the nodules are made up of groups of fungi, surrounded by granulation tissue. (3) The cases with more extensive destructive disease of the lungs, broncho-pneumonia, interstitial changes, and abscesses, the latter forming cavities large enough to be diagnosed during life. Actinomycotic lesions of other organs are often present; erosion of the vertebræ, necrosis of the ribs and sternum, with nodelike formations, subcutaneous abscesses, and occasionally general metastases.

The fever is irregular and depends largely on the existence of suppuration. The cough is an important symptom and there may be recurring hæmoptysis. Lung involvement is usually basal and there may be marked pleural thickening. Pleurisy with effusion sometimes occurs; the fluid may be purulent. Death results usually with septic symptoms but recovery is not very rare. Clinically the disease closely resembles pulmonary tuberculosis and fetid bronchitis. The diagnosis is made by finding actinomycetes in the sputum. Radiating leptothrix threads from the mouth may present a striking resemblance.

(c) **CUTANEOUS ACTINOMYCOSIS.**—In more than half of the recorded cases the disease has involved the skin of the head and neck; the buccal, lingual and pharyngeal structures may be involved also. It is a very chronic affection, which may suggest syphilis or lupus, associated with the growth of tumors which suppurate and leave open sores, which may remain for years. The characteristic yellow granules are found in the pus.

(d) **CEREBRAL ACTINOMYCOSIS.**—Bollinger reported an instance of primary disease of the brain with the symptoms of tumor. Brain abscesses are usually metastatic. In a case, reported by Keller, there was *empyema necessitatis*, which was opened and actinomycetes were found in the pus. Subsequently she had Jacksonian epilepsy, caused by abscesses which contained actinomycetes grains. Death occurred after the second operation.

(e) **RENAL ACTINOMYCOSIS.**—This is rare. Cecil and Hill in reporting a case (1922) found only 10 others in the literature.

Prognosis.—Much depends on early diagnosis and treatment and the situation is of importance as cases with involvement of the face and neck have a relatively favorable outlook. The pulmonary cases are very serious and death usually occurs. Of the cases with abdominal infection about half recover.

Diagnosis.—To remember the possibility of actinomycosis and look for it are the essentials. The yellow granules are suggestive, and microscopic examination gives the diagnosis promptly. Tuberculosis, syphilis and sarcoma have to be kept in mind to be distinguished. The tendency in actinomycosis to chronic suppuration should excite suspicion. The serum agglutination reaction is of some value.

Treatment.—This is surgical if suppuration has occurred. Incision, removal of dead tissue, and thorough irrigation are appropriate measures. Iodine should be applied locally whenever possible and iodide given in doses of 40 to 60 grains (2.5 to 4 gm.) daily. This has proved curative in a number of cases. The injection of 1 per cent. copper sulphate solution in small amounts into infiltrated areas until softening occurs has been useful. The X-rays and radium have been successful. The use of an autogenous vaccine has proved helpful in chronic cases.

II. SPOROTRICHOSIS

Definition.—A chronic infection with cutaneous and internal lesions due to various forms of parasitic fungi of the sporotrichosis group.

History.—In November, 1896, a patient presented himself at Finney's outpatient clinic at the Johns Hopkins Hospital with an infection of the right arm, which had lasted for several weeks. There were ulcerations on the hand and indurations on the forearm. The condition was recognized as unusual and Schenck, who undertook its study, found on culture a branched mycelium with numerous spores or conidia. Its identification was made by the well-known expert, Erwin F. Smith, and it was named *Sporotrichum schenckii*. Since then, the disease has been widely recognized, owing chiefly to the studies of Beurmann and Gougerot, and it is now evident that it is widely distributed and one of the most clearly defined of the mycoses.

The Parasite.—In the tissues and in the pus the parasite is a large short rod from 3 to 5 μ long and from 2 to 3 μ in breadth. In cultures it grows in filaments of about 2 μ in diameter and forms characteristic ovoid spores. The points of differentiation between the forms are due largely to variation in the modes of sporulation. The parasite is introduced chiefly by accidental inoculation, and possibly through grains and fruit. The spores have been found in the blood. The fungi have an identical action with the pathogenic bacteria, producing toxins towards which there are active humoral reactions. Widal and Abrami determined the agglutinating and fixation properties of the serum in individuals affected, and specific reactions have been determined. There are minor differences between the form described by Schenck and that described by Beurmann.

Clinical Forms.—There are several forms: (1) The disseminated *gummatous* form in which in the subcutaneous tissues in various parts of the body there are small, firm, solid nodules, which break down and form small abscesses which may ulcerate. (2) In the *ulcerative* type the lesions are not unlike those of cutaneous tuberculosis, occurring commonly on the hands and arms, though they may appear on the legs or on the body. They may be single or in groups of two or three, and in several cases seen in Paris they resembled very much eroded syphilitic gummata. (3) There is a *localized* lesion, a hard chancroid body, eroded on the surface. Dissemination occurs through the lymphatics, the regional glands become involved and there may be a group of open sores along the arm or on the side of the head. (4) There are certain *extra-cutaneous forms*—ulcerous lesions of the mucous membranes, gummata of the muscles, glands, lungs and periostitis with osteitis. (5) The disease may generalize in the internal organs and there are acute febrile forms.

The disease is essentially chronic, lasting often for a year or two; sometimes disturbing the health very slightly, and other times leading to anæmia. There may be no fever, but instances of acute attacks have been reported.

Diagnosis.—This has to be made from tuberculosis, syphilis, and actinomycosis, which may be done by cultures (as the parasites grow in a very specific way) and by agglutination and the complement fixation reaction, the full details of which are given in Beurmann's and Gougerot's manual.

Treatment.—Iodide of potassium should be given in large doses and ulcerated lesions painted with tincture of iodine. Closed abscesses may be aspirated and injected with a weak iodide solution. Active surgical interference is not advisable.

III. NOCARDIOSIS

J. H. Wright of Boston separated this group from the actinomycoses and the streptothrix infections. On the one hand the parasites resemble bacteria, on the other hand the hypomycetes or moulds, in forming branching, thread-like filaments and in the production of fine conidia. They represent a transition between the bacteria and the lower fungi. The majority of reported cases have had the signs and symptoms of pulmonary tuberculosis or of multiple abscesses. In the lungs nodules, caseous masses and lesions not unlike tubercle have been found. In some cases there was abscess of the brain. The parasite may be recognized by the typically branched filaments and by the growth in cultures.

IV. BLASTOMYCOSIS

Definition.—Under this term various infections due to blastomycetes or yeast-like organisms are included (*Saccharomyces*, *Oidium*, *Coccidioides*, *Monilia* and *Cryptococcus*). The lesions may be local or general.

Pathology.—The essential lesion is a granuloma which may break down with resulting abscess or ulceration. The lungs are involved in some cases; a secondary meningitis has been described and infiltrations have been found in the liver, spleen and lymph-nodes.

Forms.—In the skin and mucous membrane infections the early lesions are described as papular or papillomatous in character which gradually enlarge and soften. The skin may be greatly thickened and abscesses are common. Sometimes there are sinuses leading to the deeper structures. The lesions are very chronic and there is always danger of extension to the viscera. In the systemic invasion the special features depend on the organ involved. Fever is common. *Coccidioidal granuloma*, which occurs particularly in California, usually begins in the skin with later involvement of the viscera. In the lungs the picture is like that of tuberculosis. *Histoplasmosis* possibly belongs here. Darling described cases in Panama due to *Histoplasma capsulati* in which nodules were found in the lungs. The prognosis is serious in all forms. The surface lesions are very chronic and death follows visceral involvement.

Diagnosis.—Syphilis and tuberculosis are suggested and have to be excluded. The finding of the causal organism gives the only certain diagnosis.

Treatment.—Excision, the cautery and the application of tincture of iodine may be tried in local lesions. The use of the X-rays or radium may be effectual, and iodide should always be given in large doses.

V. TORULOSIS

This is due to infection by Torula, a yeast which multiplies by budding, does not ferment carbohydrates and does not produce a mycelium in tissue or culture. The infection occurs most often in the nervous system. Shapiro and Neal (1925) found 15 cases (13 in the nervous system). The symptoms are varied, depending on the parts attacked. In the nervous system meningitis or brain tumor is simulated. In the lungs the picture may suggest tuberculosis or tumor. Acute miliary torulosis of the lungs may occur. In diagnosis this infection should be distinguished from blastomycosis. There is no special treatment and the prognosis is grave.

VI. MYCETOMA

Vandyke Carter of Bombay, a pioneer in the study of tropical diseases, gave an admirable description of this affection, which prevails largely in certain districts of India, and sporadically in other parts of the world.

The disease, usually involving the foot (hence the term *Madura Foot*), is characterized by great swelling, nodular growths and the formation of multiple abscesses. There are remarkable granules 1 mm. in diameter, usually of a black color, in the discharges; in other cases the granules are yellow or brownish. In the pale variety a streptothrix has been found, which closely resembles actinomyces. It is held by most observers that this streptothrix and actinomyces are distinct species. From the black variety of granules a hypomycete has been grown, closely allied to aspergillus.

The disease begins as a granuloma, with swelling of the foot, generally on the sole. The tumors gradually soften, others form, the foot increases enormously in bulk, becomes much deformed, numerous sinuses pass between the bones, the discharges are muco-purulent and contain the characteristic granules. Treatment by the use of the X-rays and the intravenous injection of antimony has been helpful. Sometimes curettng or early excision is useful or, in later stages, amputation of the foot may be necessary.

VII. ASPERGILLOSIS

Bennett in 1842 described the parasite from the lungs, the *Aspergillus fumigatus*, a fungus widely distributed as a harmless parasite, having been found in the auditory canal, nose and throat. In birds, in cattle, more rarely in dogs, the aspergillus may cause lesions of the lungs resembling tuberculosis, and there have been some cases reported in man, particularly in pigeon keepers and hair sorters. The infection is usually secondary to some long-standing affection of the lungs, but it has been met with as a primary disease with lesions resembling broncho-pneumonia, which undergo necrosis and softening and the clinical picture is that of ordinary tuberculosis.

The symptoms are those of chronic pulmonary disease, cough, fever, and expectoration, in which the aspergillus is found. It is readily recognized by

the character of its spores. In the case reported by the senior author, at intervals of two or three months for twelve years the patient coughed up, usually with a good deal of difficulty, a grayish-brown mass the size of a small bean, which was made up entirely of the mycelium and spores of the aspergillus. The interesting point was that the patient had no symptoms, other than the cough, and was in excellent health. In the majority of cases the outlook is bad, and the treatment is that of chronic tuberculosis.

C. PROTOZOAN INFECTIONS

I. PSOROSPERMIASIS

Though widely spread in invertebrates, pathogenic psorosperms are not common in mammals, and in man serious disease is very rarely caused by them. One of the commonest forms of psorosperm is the so-called Rainey's tube, an ovoid body found in the muscle of the pig, filled with small sickle-shaped unicellular organisms, *Sarcocystis miescheri*. In a few instances similar structures have been found in the muscles of man. The only human parasite of this group which has caused serious disease belongs to the coccidia. The parasite is *Coccidium oviforme*, which is common in rabbits and mice.

Coccidiosis.—In a majority of the cases of this group the psorosperms have been found in the liver, producing a disease similar to that in rabbits. In Guebler's case there were tumors which could be felt during life, and they were determined by Leuckart to be due to coccidia. A patient of W. B. Haddon's had slight fever and drowsiness, and gradually became unconscious—death occurring on the fourteenth day of observation. Whitish neoplasms were found upon the peritoneum, omentum, and on the layers of the pericardium; and a few were found in the liver, spleen, and kidneys. A somewhat similar case with a very acute course, is reported by Silcott. A woman, aged fifty-three, had a chill six weeks before admission. She showed fever of an intermittent type, slight diarrhoea, nausea, tenderness over the liver and spleen, and a dry tongue; death occurred from heart-failure. The liver was enlarged, weighed 83 ounces, and in its substance there were caseous foci, around each of which was a ring of congestion. The spleen weighed 16 ounces and contained similar bodies. The masses resembled tubercles, but on examination coccidia were found.

The parasites are also found in the kidneys and ureters. In Eve's case the symptoms were hæmaturia and frequent micturition, and death took place on the seventeenth day. The nodules throughout the pelvis and ureters have been regarded as mucous cysts. There is no special treatment.

II. AMOEBIASIS

(*Amœbic Dysentery, Amœbic Hepatitis*)

Definition.—A colitis, acute or chronic, caused by *Entamoeba histolytica* with a special liability to the formation of abscesses of the liver.

Distribution.—The disease is widely prevalent in Egypt, in India and in tropical countries. In Europe sporadic cases occur, rarely small epidemics.

It is uncommon in Great Britain. It is common in the southern United States, where it is endemic, increasing sometimes to epidemic proportions. Sporadic cases occur in all temperate regions. The relative frequency of this form of dysentery in the tropics is illustrated by the Manila statistics given by Strong; of 1,328 cases in the U. S. Army, 561 were of the amoebic variety. There are at least five species of amœbæ found in man, *Entamœba histolytica* (pathogenic) and *E. coli*, *Endolima nana*, *Iodamœba bütschlii* and *Dientamœba fragilis*, which are non-pathogenic. These harmless forms have been found very commonly.

AGE.—It is not uncommon in children but the greatest number of cases occur between the ages of 20 and 35.

SEX.—Males are much more frequently affected. Of 182 cases at the Johns Hopkins Hospital 171 were males (Fletcher).

RACE.—The white race is more susceptible, 163 whites to 19 blacks in the Johns Hopkins Hospital series. In the Philippines the whites are more often attacked. In India the disease is common in the native races.

The Amœba.—The *Entamœba histolytica* was first described by Lambl in 1859 and subsequently by Lösch in 1875. Kartulis in 1886 found them in the stools of the endemic dysentery in Egypt and in the liver abscesses. In 1890 the senior author found them in a case of dysentery with abscess of the liver originating in Panama. Subsequently from his wards a series of cases was described by Councilman and Lafleur. The studies of Quinke and Roos, of Dock, Harris and others in the United States, of Strong and Musgrave in the Philippines, of Kruse and Pasquale in Egypt and of Leonard Rogers in India have put our knowledge of the disease on a firm basis. To find the amœbæ the little flakes of mucus or pus in the stools should be selected for examination or the mucus obtained by passing a soft rubber tube.

Entamœba histolytica is from 15 to 20 μ in diameter, has a clear outer zone (ectosarc) and a granular inner zone (endosarc). The nucleus is seen with difficulty and contains little chromatin. The movements are similar to those of the ordinary pond amœba, consisting of slight protrusions of the protoplasm. They vary a good deal, and usually may be intensified by having the slide heated. Not infrequently the amœbæ contain red blood corpuscles. In the tissues they are very readily recognized by suitable stains. In the pus of a liver abscess they may be very abundant, though in large, long standing abscesses they may not be found until after a few days, when the pus begins to discharge from the wall. In the sputum in the cases of pulmonary abscess they are readily recognized.

The parasite occurs in two forms: (a) motile or vegetative stage and (b) cystic stage. The latter may be found in semi-formed or formed stools. The recognition of the vegetative organism is aided by vital staining with a 1 per cent. aqueous solution of neutral red. The vegetative amœbæ die rapidly after a stool is passed and so probably play little part in the transmission of the disease. The cysts may be difficult to recognize. Culture methods and sedimentation may aid. Emulsifying the feces in Gram's iodine solution or the iodine-eosin method is useful. The encysted forms are responsible for the spread of the disease and their occurrence in carriers is of great importance. Infection occurs by food or water and flies may convey the infection. Some authorities believe that there are numerous carriers in temperate climates.

They may have loose stools only occasionally but show a variety of symptoms, malaise, anorexia, alternating constipation and diarrhœa, abdominal discomfort or pain relieved by a loose stool, abdominal distention, and mucous stools.

Morbid Anatomy.—**INTESTINES.**—The lesions consist of ulceration, produced by preceding infiltration of the submucosa, due to an œdematous condition and to multiplication of the fixed cells. In the earliest stage these local infiltrations appear as hemispherical elevations above the general level of the mucosa. The mucous membrane over these becomes necrotic and is cast off, exposing the infiltrated submucous tissue as a grayish yellow gelatinous mass, which at first forms the floor of the ulcer, but is subsequently cast off as a slough. The individual ulcers are round, oval, or irregular, with infiltrated, undermined edges. The visible aperture is often small compared to the loss of tissue beneath it, the ulcers undermining the mucosa, coalescing, and forming sinuous tracts bridged over by apparently normal mucous membrane. The floor of the ulcer may be formed by the submucous, muscular, or serous coat of the intestine. The ulceration may affect the whole or some portion only of the large intestine, particularly the cæcum, the hepatic and sigmoid flexures, and the rectum. In severe cases the whole of the intestine is much thickened and riddled with ulcers, with here and there islands of intact mucous membrane. In 100 autopsies in Manila the appendix was involved in 7; perforation of the colon took place in 19.

The disease advances by progressive infiltration of the connective tissue layers of the intestine, which produces necrosis of the overlying structures. Thus, in severe cases there may be in different parts of the bowel sloughing *en masse* of the mucosa or of the muscularis, and the same process is observed, but not so conspicuously, in the less severe forms. In some cases a secondary diphtheritic inflammation occurs. Healing takes place by the gradual formation of fibrous tissue in the floor and at the edges of the ulcers, which may result in partial and irregular strictures of the bowel.

Microscopic examination shows a notable absence of the products of purulent inflammation. In the infiltrated tissues polynuclear leucocytes are seldom found, and never constitute purulent collections. On the other hand, there is proliferation of the fixed connective-tissue cells. Amœbæ are found more or less abundantly in the tissues at the base of and around the ulcers, in the lymphatic spaces, and occasionally in the blood-vessels. The portal capillaries occasionally contain them, and this fact seems to afford the best explanation for the mode of infection of the liver.

LIVER.—The lesions are of two kinds: first, local necroses of the parenchyma, scattered throughout the organ and, secondly, abscesses. These may be single or multiple. There were 37 cases of hepatic abscess among the 182 cases of amœbic dysentery in the Hopkins Hospital. Of these, 18 came to autopsy. In 10 the abscess was single and in 8 multiple. When single they are generally in the right lobe, either toward the convex surface near its diaphragmatic attachment or on the concave surface in proximity to the bowel. Multiple abscesses are small and generally superficial. There may be innumerable miliary abscesses containing amœbæ scattered throughout the organ. Although the hepatic abscess usually occurs within the first two months from the onset of the dysentery, in one case the latter had lasted one and in another six years. In 5 cases the intestinal symptoms had been so slight that no

complaint of dysentery had been made. In an early stage the abscesses are grayish yellow, with sharply defined contours, and contain a spongy necrotic material, with more or less fluid in its interstices. The larger abscesses have ragged necrotic walls, and contain a viscid, greenish yellow or reddish yellow purulent material mixed with blood and shreds of liver tissue. The older abscesses have fibrous walls of a dense, almost cartilaginous toughness. There is the same absence of purulent inflammation as in the intestine, except when a secondary infection with pyogenic organisms has taken place.

LESIONS IN THE LUNGS are seen when an abscess of the liver points toward the diaphragm and extends by continuity through it into the lower lobe of the right lung. This is the commonest situation for rupture to occur. Rupture may occur into the right pleura, causing empyema or a lung abscess may rupture into the pleura, producing a pyo-pneumothorax. Perforation may occur into *adjacent structures*. In 3 of our cases perforation took place into the inferior vena cava and in another the upper pole of the right kidney was invaded. The abscess may rupture into the pericardium, peritoneum, stomach, intestine, portal and hepatic veins, or externally. The lungs may be involved directly without extension from the liver.

Amœbæ have been reported as occurring in many parts of the body but many of these are undoubtedly incorrect. Warthin reported a case in which *Ent. histolytica* was found in the testis and epididymis with tissue lesions.

Symptoms.—Three groups of cases may be recognized:

MILD FORM.—Infection may be present for a month or two before the individual is aware of it. There may be vague symptoms—headache, lassitude, weakness, slight abdominal pains and occasional diarrhœa, features common enough in the tropics. Latency is the feature in a large number of cases. The amœbæ may be present without exciting symptoms, or there may be slight transient attacks of diarrhœa, and yet in these cases hepatic abscess may follow. There is evidence to suggest that infection without symptoms is present in a number (some suggest 10 per cent.) of the population. The infrequency of acute cases in temperate regions suggests that the danger is slight.

ACUTE AMŒBIC DYSENTERY.—Many cases have an acute onset. Pain and tenesmus are common. The stools are bloody, or mucus and blood occur together. In very severe cases there may be constant tenesmus, with pain of the greatest intensity, and the passage every few minutes of a little blood and mucus. In some cases large sloughs are passed. The temperature as a rule is not high. The patient may become rapidly emaciated; the heart's action becomes feeble, and death may occur within a week of the onset. *Hæmorrhage* from the bowels and *perforation* of an ulcer with general peritonitis occur in some cases. A majority of the patients recover; in others the disease drags on and becomes chronic, the symptoms often showing a periodicity. In a few cases, after the separation of the sloughs, there is extensive ulceration remaining, with thickening and induration of the colon, and the patient has constant diarrhœa, loses weight, and ultimately dies exhausted, usually within three months of the onset. With the exception of cancer of the œsophagus and anorexia nervosa, no such extreme emaciation is seen. Extensive ulceration of the cornea may occur.

CHRONIC AMŒBIC DYSENTERY.—The disease may be subacute from the onset, and gradually passes into a chronic stage, the special characteristic of

which is alternating periods of constipation and of diarrhœa. These may occur over a period of from six months to a year or more. Some of our patients were admitted to the hospital five or six times within a period of two years. During the exacerbations there are pain, frequent passages of mucus and blood, and a slight rise of temperature. Many patients do not feel very ill, and retain their nutrition in a remarkable way; indeed, in the United States it is rare to see the extreme emaciation so common in the chronic cases from the tropics. Alternating periods of improvement with attacks of diarrhœa are the rule. The appetite is capricious, the digestion disordered, and slight errors in diet are apt to be followed at once by an increase in the number of stools. The tongue is often red, glazed, and beefy.

Complications and Sequelæ.—**LIVER ABSCESS.**—A pre-suppurative stage lasting for several weeks or months is recognized by Rogers, characterized by fever of an intermittent type, moderate leucocytosis, and an enlarged and tender liver. Suppuration in the liver is the most serious and frequent complication. Abscess of the brain has occurred.

Perforation of the intestine and *peritonitis* occurred in three of our cases. *Intestinal hæmorrhage* occurred three times. The infrequency of this complication is probably due to the thrombosis of the vessels about the areas of infiltration. Polypoid colitis may be a late manifestation (Hines). Occasionally an *arthritis*, probably toxic in origin, may occur. Five cases were complicated by malaria; 1 by typhoid fever; 1 by pulmonary tuberculosis; and 1 by a strongyloides intestinalis infection.

Urinary Amœbiasis.—Macfie reports a case and states that there are about a dozen instances in the literature. In the majority the infection has been with *Ent. histolytica*. The infection may be of the kidney, bladder, seminal vesicles or urethra. Amœbæ have been found in the seminal fluid. The process may be a primary infection or secondary to amœbic dysentery.

Diagnosis.—From the other forms of dysentery the disease is recognized by the finding of amœbæ or cysts in the stools. Unless one sees undoubted amœboid movement a suspected body should not be considered an amœba. A non-motile body containing one or more red cells is probably an amœba, but should lead to further search for motile organisms. Swollen epithelial cells are confusing, but the hyaline periphery is not amœboid. The trichomonads and cercomonads so frequently associated with amœbæ are not likely to give trouble. The *Ent. histolytica* is distinguished from non-pathogenic forms by its larger size, distinct refractile ectoplasm, faint nucleus, marked mobility, vacuoles, contained red blood cells, and scanty chromatin in the nucleus. The cysts are small and do not contain more than four nuclei. In the cysts of *Ent. coli* the nuclei are eight or more. Various stains are an aid in differentiation. Craig has devised a complement fixation test. The extent of liver dulness should be watched and any increase should lead to the suspicion of abscess. Hepatic abscess is usually accompanied by fever, sweats, or chills and local pain, but may be entirely latent. A varying leucocytosis occurs in the abscess cases. The highest count in our series was 53,000, the average being 18,350. The average leucocyte count in the uncomplicated dysentery cases was 10,600. Hepato-pulmonary abscess is attended by local lung signs and the expectoration of "anchovy sauce" sputum in which amœbæ are almost invariably found.

Prognosis.—In many cases the disease yields to treatment, especially if begun early, but the tendency to relapse is a striking characteristic. Some patients are very resistant to treatment. Amœbic abscess is always serious.

Treatment.—Rest in bed is very important, even in mild attacks, and materially hastens recovery. The diet should be governed by the severity of the intestinal manifestations. In the very acute cases the patient should be given a liquid diet, consisting of milk, whey, and broths.

A return to the use of ipecacuanha (emetine) is the most important event of the late years in the treatment of this form of dysentery. It should always be tried, even in chronic cases. Emetine hydrochloride hypodermically is given in doses of $\frac{1}{2}$ grain (0.03 gm.) twice a day for six days or 1 grain (0.06 gm.) daily for twelve days. This course should be repeated if necessary. Emetine sometimes causes diarrhœa which may be mistaken for the original dysentery. The same treatment should be given to prevent liver abscess when there is a suspicion of hepatitis. Another preparation is emetine bismuth iodide given in keratin capsules in doses of gr. ii-iii (0.12-0.18 gm.) each night for twelve doses. Some patients do better with ipecacuanha given at night in salol coated pills or keratin capsules; the first dose is 60 gr. (4 gm.) reduced by five grains each night until it is down to ten grains (0.6 gm.). Some advise emetine hypodermically and ipecac by mouth at the same time.

Bismuth probably does more harm than good, as it coats the surface of the ulcers. It is well in the chronic forms to give an occasional dose of saline or castor oil. Large injections of quinine solution in the strength of 1 to 5,000, gradually increasing to 1 to 500, give the most satisfactory results of the local remedies. The amœbæ are rapidly destroyed by the drug. The success of the treatment depends largely on the care with which the injections are given. From a litre to two litres should be given. The patient's hips should be elevated and he should change his position so as to allow the fluid to flow into all parts of the colon. The solution should be retained, if possible, for fifteen minutes. One or two injections may be given daily. Injections of silver nitrate solution (1 to 2,000, increased to 1 to 500) are useful in chronic cases. When there is much tenesmus a starch and laudanum enema gives great relief. Hot applications to the abdomen are grateful.

The drug known by the trade name of "Yatren" is given by mouth (gr. vi, 0.4 gm. three times a day for ten days) and by bowel irrigation (250 c. c. of a 2.5 per cent. solution, retained for some hours if possible) once a day for ten days. It is said to act on the cysts. Stovarsol is given in doses of 4 grains (0.25 gm.) three times a day for a week and then once a day for ten days. Arsenobenzol has been given intravenously in doses of 0.15 to 0.3 gram.

When medical treatment fails, cæcostomy may be tried or irrigations given through the appendix.

The treatment of *carriers* is a different problem. The use of emetine bismuth iodide as mentioned has proved of value. Others advise the oil of chenopodium given after free purgation. An ounce of epsom salts is given at 6 A. M., oil of chenopodium in capsules (℥ xv, 1 c. c.) at 8 and 10 A. M., and noon; castor oil ʒi (30 c. c.) with 50 minims of chloroform at 2 P. M.

Hepatic abscess may be drained and the cavity irrigated by quinine solution (1 to 1,000). Emetine should be given as advised for the dysentery. Repeated aspiration of the abscess with the use of emetine has been successful.

III. MALARIAL FEVER

Definition.—A protozoal disease with: (a) paroxysms of intermittent fever of quotidian, tertian, or quartan type; (b) a continued fever with marked remissions; (c) certain pernicious, rapidly fatal forms; and (d) a chronic cachexia, with anæmia and enlarged spleen.

Hæmosporidia, genus *Plasmodium*, transmitted to man by the bite of anopheline mosquitoes, are invariably associated with the disease. Malaria occurs as an endemic and epidemic disease, the latter prevailing in the tropics under favoring conditions. No infection except, perhaps, tuberculosis compares with it in the extent of its distribution or its importance as a killing and disabling disease.

Geographical Distribution.—In Europe, southern Russia and parts of Italy and Greece are the chief seats of the disease. It is rare in Germany, France, and England, and the foci of epidemics are becoming more restricted. In the United States malaria has progressively diminished in extent and severity during the past fifty years. From New England, where it once prevailed extensively, it has gradually disappeared and in New York even the milder forms of the disease are rare. In Philadelphia and along the valleys of the Delaware and Schuylkill Rivers, formerly hot-beds of malaria, the disease has become much restricted. In Baltimore a few cases occur in the autumn, but a majority of the patients are from the outlying districts. Throughout the Southern States there are many regions in which malaria prevails; but here, too, the disease has diminished in prevalence and intensity. In temperate regions, like the central Atlantic states, there are only a few cases in the spring, usually in May, and more cases in the autumn. In the northwestern states malaria is almost unknown. The St. Lawrence basin remains free from the disease.

In India the disease is very prevalent, particularly in the great river basins. Terrible epidemics occur. In the Punjab in 1908 there were more than three million deaths from fever, a large proportion of which were from malaria. In Burma and Assam severe types are met with. In Africa the malarial fevers form the great obstacle to European settlements on the coast and along the river basins. The *black-water fever* is a very fatal type of malarial hæmoglobinuria. The Atlantic coast line of Central America is severely infected, and the Isthmus of Panama for centuries was known as the "white man's grave." In the tropics there are minimal and maximal periods, the former corresponding to the summer and winter, the latter to the spring and autumn months.

Etiology: The Parasite.—**HISTORY.**—Parasites of the red blood corpuscles are very widespread throughout the animal series. They are met with in the blood of frogs, fish, birds, and among mammals in monkeys, bats, cattle, and man. In birds and in frogs the parasites appear to do no harm except when present in very large numbers.

In 1880 Laveran, a French army surgeon stationed at Algiers, noted in the blood of patients with malarial fever pigmented bodies, which he regarded as parasites, and as the cause of the disease. Richard, another French army surgeon, confirmed these observations. In 1885 Marchiafava and Celli de-

scribed the parasites with great accuracy, and Golgi made the all-important observation that the paroxysm of fever invariably coincided with the sporulation or segmentation of a group of the parasites. In the following year (1886) Laveran's observations were brought before the profession of the United States by Sternberg. Councilman and Abbott had in the previous year described the pigmented bodies in the red blood corpuscles in the blood vessels of the brain in a fatal case, and in 1886 Councilman confirmed the observations of Laveran in clinical cases. Stimulated by his work, the senior author began studying the malarial cases in the Philadelphia Hospital, and soon became convinced of the truth of Laveran's discovery, and confirmed Golgi's statement as to the coincidence of the sporulation with the paroxysm. The work was taken up actively in the United States by Walter James, Dock, Koplik, Thayer, Hewetson, and others, and in many communications the extraordinary clinical importance of Laveran's discovery was emphasized.¹

Among British observers, Vandyke Carter alone, in India, seems to have appreciated at an early date the profound significance of Laveran's work.

The next important observation was the discovery by Golgi that the parasite of quartan malarial fever differed from the tertian. From this time on the Italian observers took up the work with great energy, and in 1889 Marchiafava and Celli determined that the organism of the severer forms of malarial fever differed from the parasite of the tertian and quartan varieties.

The connection of insects with the disease is an old story suggested in Roman times and revived by John Crawford, of Baltimore (1807), King, of Washington, and settled finally by Ross. The idea that fever was transmitted by the bite of the mosquito prevailed widely in the West Indies and in the Southern States. The important rôle played by insects as an intermediate host had been shown in Texas cattle fever, in which Theobald Smith demonstrated that the hæmatozoa developed in, and the disease was transmitted by, ticks; but it remained for Manson to formulate in a clear and scientific way the theory of infection in malaria by the mosquito. Impressed by this, Ross studied the problem in India, and showed that the parasites developed in the bodies of the mosquitoes, demonstrating conclusively that the infection in birds was transmitted by the mosquito. W. G. MacCallum suggested that the flagella were sexual elements, and observed the process of fertilization by them. Studies by Grassi, Bastianelli and Bignami, and many others, confirmed the observations of Ross and demonstrated that the malarial parasites of human beings develop only in mosquitoes of the genus anopheles.

Then came the practical demonstration by Italian observers, and by the interesting experiments on Manson, Jr., of the direct transmission of the disease to man by the bite of infected mosquitoes. And lastly, as a practical conclusion of the whole matter, the anti-malarial campaigns so energetically

¹ The following references to work on malaria which has been done in connection with the Hopkins clinic, chiefly under the supervision of Professor Thayer, may be of interest: Phila. Med. Times, 1886; British Med. Jour., March, 1887; Med. News, 1889, vol. i; Johns Hopkins Hosp. Bull., 1889; the first edition of this Text-Book of Medicine, 1892; Thayer and Hewetson, Johns Hopkins Hosp. Rep., 1895; Thayer, Lectures on Malarial Fever, 1897; W. G. MacCallum, Hæmatozoa of Birds, Jour. of Exp. Med., 1898; Opie, on the Hæmatozoa of Birds, 1898; Barker, on Fatal Cases of Malaria, Johns Hopkins Hosp. Rep., 1899; MacCallum, on the Significance of the Flagella, Lancet, 1897; Thayer, Trans. Am. Med. Con., vol. iv, 1900; Lazear, Structure of the Malarial Parasites, Johns Hopkins Hosp. Rep., 1902.

advocated and carried out by Ross have shown that by protecting the individual from the bites of mosquitoes, by exterminating the insects, or by carefully treating all patients so that no opportunity may be offered for the parasite to enter the mosquito, malaria may be eradicated from any locality.

THE PARASITE.—Belonging to the sporozoa, it has received a large number of names. The term *Plasmodium*, inapt though it may be, must, according to the rules of zoological nomenclature, be applied to the human parasite. There are three well-marked varieties which exist in two separate phases or stages: (a) The parasite in man, who acts as the intermediate host, and in whom, in the cycle (asexual) of its development, it causes symptoms of malaria; and (b) an extracorporeal cycle (sexual), in which it lives and develops in the body of the mosquito, which is its definitive host. The parasites have been grown in artificial media (Bass).

(a) *The Parasite in Man.*—(1) Tertian Fever (*Plasmodium vivax*).—The earliest form seen in the red blood corpuscle is round or irregular in shape, about $2\ \mu$ in diameter and unpigmented. It corresponds very much in appearance with the segments of the rosettes formed during the chill. A few hours later the body has increased in size, is still ring-shaped, and there is pigment in the form of fine grains. It has a relatively large nuclear body, consisting of a well-defined, clear area, in part almost transparent, in part consisting of a milk-white substance, in which there lies a small, deeply staining chromatin mass. At this period it usually shows active amœboid movements, with tongue-like protrusions. The pigment increases in amount and the corpuscle becomes larger and paler, owing to a progressive diminution of its hæmoglobin. There is a gradual growth of the parasite, which, toward the end of forty-eight hours, occupies almost all of the swollen red corpuscle. It is now much pigmented, and is in the stage called the full-grown parasite. Between the fortieth and forty-eighth hours many of the parasites undergo segmentation, in which the pigment becomes collected into a single mass, and the protoplasm divides into fifteen to twenty spores, often showing a radial arrangement. Certain full-grown tertian parasites, however, do not undergo segmentation. These forms, which are larger than the sporulating bodies, and contain very actively dancing pigment granules, represent sexually differentiated form of the parasite—gametocytes.

(2) Quartan fever (*Plasmodium malarie*).—The earliest form is very like the tertian but as it increases in size the granules are coarser and darker and the movement is not nearly so marked. By the second day the parasite is still larger, rounded in shape, scarcely at all amœboid, and the pigment is more often arranged at the periphery of the parasite. The rim of protoplasm about it is often of a deep yellowish-green color or of a dark brassy tint. On the third day the segmenting bodies become abundant, the pigment flowing in toward the centre of the parasite in radial lines so as to give a star-shaped appearance. The parasites finally break up into from six to twelve segments. Here also, as in the case of the tertian parasite, some full-grown bodies persist without sporulating, representing the gametocytes.

(3) *Æstivo-Autumnal Fever* (*Plasmodium falciparum*).—This parasite is considerably smaller than the other varieties; at full development it is often less than one-half the size of a red blood corpuscle. The pigment is much scantier, often consisting of a few minute granules. At first only the

earlier stages of development, small, hyaline bodies, sometimes with one or two pigment granules, are to be found in the peripheral blood; the later stages are ordinarily to be seen only in the blood of certain internal organs, the spleen and bone marrow particularly. Some workers believe that there are two varieties of this form, tertian and quotidian (*P. falciparum quotidianum*). The corpuscles containing the parasites frequently become shrunken, crenated, and brassy-colored. After the infection has existed for about a week, larger, refractive, crescentic, ovoid, and round bodies, with central clumps of coarse pigment granules, begin to appear. These bodies are characteristic of æstivo-autumnal fever. The crescentic and ovoid forms are incapable of sporulation; they are analogous to the large, full-grown, non-sporulating bodies of the tertian and quartan parasites and represent sexually differentiated forms—gametocytes. Within the human host they are incapable of further development, but upon the slide, or within the stomach of the intermediate host, the mosquito, the male elements (micro-gametocytes) give rise to a number of long, actively motile flagella (micro-gametes) which break loose, penetrating and fecundating the female forms—macro-gametes (W. G. MacCallum). The fecundated female form enters into the stomach wall of the mosquito, where it undergoes a definite cycle of existence.

A subspecies of *P. vivax* has been described, termed *P. vivax minutum*, and a species closely resembling *P. falciparum*, termed *P. tenue*, has been identified by Stephens.

(b) *The Parasite in the Mosquito*.—The brilliant researches of Ross, followed by the work of Grassi, Bastianelli, Bignami, Stephens, Christophers, and Daniels, proved that a certain genus of mosquito—anopheles—is not only the definitive host of the malarial parasite, but also the sole source of infection. The more common genera of mosquito in temperate climates are culex and anopheles. The different species of culex form the majority of our ordinary house mosquitoes, and are incapable of acting as hosts of the malarial parasite. All malarial regions which have been investigated contain anopheles but they may be present without the existence of malaria under two circumstances: first, when the climate is too cold for the development of the malarial parasite; and secondly, in a region which has not yet been infected. So far as is known, the parasite exists only in the mosquito and in man.

A large number of species of anopheles have been described in different parts of the world. In North America the commonest variety and that in all probability most concerned in the spread of the disease is *A. maculipennis*, which is, also, the most important agent in the spread of the disease in Europe. The culex lays its eggs in sinks, tanks, cisterns, and any collection of water about or in houses, while the anopheles lays its eggs in small, shallow puddles or slowly running streams, especially those in which certain forms of algæ exist. The culex is essentially a city mosquito, the anopheles a country insect.

Evolution in the Mosquito.—When a mosquito of the genus anopheles bites an individual whose blood contains sex-ripe forms (gametocytes) of the malarial parasite, flagellation and fecundation of the female element occur within the stomach of the insect. The fecundated element penetrates the wall of the mosquito's stomach and begins a definite cycle of development in the muscular coat. Two days after biting there begin to appear small, round,

refractive, granular bodies in the stomach wall of the mosquito, which contain pigment granules clearly identical with those previously contained in the malarial parasite. These develop until at the end of seven days they have reached a diameter of from 60 to 70 μ . At this period they show a delicate radial striation due to the presence of great numbers of small sporoblasts. The mother oöcyst (zygote) then bursts, setting free into the body cavity of the mosquito an enormous number of delicate spindle-shaped sporozooids. These accumulate in the veneno-salivary glands of the mosquito, and, escaping into the ducts, are inoculated with subsequent bites of the insect. These little spindle-shaped sporozooids develop, after inoculation into the warm-blooded host, into young parasites. The sporozooid which has developed in the oöcyst in the stomach wall of the mosquito is the equivalent of the spore resulting from the asexual segmentation of the full-grown parasite in the circulation. Either one, on entering a red blood corpuscle, may give rise to the asexual or sexual cycle. As a rule the first several generations of parasites in the human body pursue the asexual cycle, the sexual forms developing later. These sexual forms, sterile in the human host, serve as the means of preserving the life of the parasite and spreading infection by the mosquito.

Morbid Anatomy.—The changes result from the disintegration of the red blood corpuscles, accumulation of the pigment thereby formed, and possibly the influence of toxic materials produced by the parasite. Cases of simple malarial infection are rarely fatal, and our knowledge of the morbid anatomy is drawn from the pernicious malaria or the chronic cachexia. Rupture of the enlarged spleen may occur spontaneously, but more commonly from trauma. Fatal hæmorrhage has followed the exploratory puncture of an enlarged malarial spleen.

PERNICIOUS MALARIA.—The blood is hydræmic and the serum may even be tinged with hæmoglobin. The red blood corpuscles present the endoglobular forms of the parasite and are in all stages of destruction. The capillaries of the brain may be filled by masses of red cells and parasites, often forming thrombi. The *spleen* is enlarged, often only moderately; thus, of two fatal cases the spleens measured 13 x 8 cm. and 14 x 8 cm. respectively. In a fresh infection the spleen is usually soft. The *liver* is swollen and turbid. In some acute pernicious cases the capillaries of the gastro-intestinal mucosa may be packed with parasites.

MALARIAL CACHEXIA.—In fatal cases of chronic paludism death occurs usually from anæmia or the hæmorrhage associated with it. The spleen may weigh from five to ten pounds. The liver may be greatly enlarged and of a grayish-brown or slate color, due to the large amount of pigment. In the portal canals and beneath the capsule the connective tissue is impregnated with melanin. The pigment is seen in the Kupffer's cells and the perivascular tissue. The kidneys may be enlarged and present a grayish-red color, or areas of pigmentation may be seen. The peritoneum is usually of a deep slate color. The mucous membrane of the stomach and intestines may have the same hue, due to the pigment in and about the blood-vessels.

ACCIDENTAL AND LATE LESIONS.—(a) *The Liver.*—Malarial hepatitis plays a very important rôle in malaria as described by French writers. Only those cases in which the history is definite, and in which the melanosis of both liver and spleen coexist, should be regarded as of malarial origin.

(b) *Pneumonia* is believed by many authors to be common in malaria, and even to depend directly upon the malarial parasite, occurring either in the acute or in the chronic forms of the disease.

(c) *Nephritis*.—Moderate albuminuria is a frequent occurrence, having occurred in 46.4 per cent. of the cases in the Johns Hopkins Hospital. Acute nephritis is relatively frequent in æstivo-autumnal infections, having occurred in over 4.5 per cent. of our cases. Chronic nephritis occasionally follows long-continued or frequently repeated infections.

Clinical Forms of Malarial Fever.—The relative frequency of the different forms varies in different regions. The tertian is the most common in temperate regions, the æstivo-autumnal in the tropics, the quartan generally rare except in certain parts of India. In the Canal Zone the relative frequency of the different forms from 1904 to January 1st, 1910, was as follows: æstivo-autumnal, 22,089; tertian, 8,013; mixed infections, 677, and quartan, 20 cases. The quartan was relatively more frequent in Baltimore; of 1,618 cases of malaria, there were 15 instances (Thayer).

I. THE REGULARLY INTERMITTENT FEVERS.—(a) Tertian fever; (b) quartan fever. These forms are characterized by recurring paroxysms, in which, as a rule, chill, fever, and sweat follow in orderly sequence. The incubation period in the tertian form is about two weeks and in the quartan form about three weeks. In patients with paresis, inoculated with *P. vivax*, the incubation period varies from 5 to 30 days. The amount of infectious material introduced influences the incubation period. On the other hand, the patient may have a paroxysm months after he has removed from a malarial region, though of course this cannot be the case unless he has had the disease when living there. The period of latency may be quite prolonged.

Description of the Paroxysm.—The patient generally knows he is going to have a chill a few hours before its advent by unpleasant feelings and uneasy sensations, sometimes by headache. The paroxysm is divided into three stages—cold, hot, and sweating.

Cold Stage.—The onset is indicated by lassitude and a desire to yawn and stretch, by headache, uneasy sensations in the epigastrium, sometimes by nausea and vomiting. Even before the chill the thermometer indicates a rise in temperature. Gradually the patient begins to shiver, the face looks cold, and in the fully developed rigor the whole body shakes, the teeth chatter, and the movements may be violent enough to shake the bed. Not only does the patient look cold and blue, but a surface thermometer will indicate a reduction of the skin temperature. The mouth or rectal temperature may, during the chill, be greatly increased, and the fever may rise to 105° or 106°. Of symptoms associated with the chill, nausea and vomiting are common. There may be intense headache. The pulse is quick, small, and hard. The urine is increased in quantity. The chill lasts for a variable time, from ten minutes to an hour, or even longer.

The *hot stage* is ushered in by transient flushes of heat; gradually the coldness of the surface disappears and the skin becomes intensely hot. The contrast in the appearance is striking: the face is flushed, the hands congested, the skin reddened, the pulse full and bounding, the heart's action forcible, and the patient may complain of a throbbing headache. There

may be active delirium. One patient in this stage jumped through a window and sustained fatal injuries. The rectal temperature may not increase much during this stage; in fact, by the termination of the chill the fever may have reached its maximum. The duration of the hot stage varies from half an hour to three or four hours.

CHART VIa.—DOUBLE TERTIAN INFECTION. QUOTIDIAN FEVER.

Sweating Stage.—Beads of perspiration appear upon the face and gradually the entire body is bathed in a copious sweat. The discomfort disappears, the headache is relieved, and within an hour or two the paroxysm is over and the patient usually sinks into a refreshing sleep. The sweating varies much. It may be drenching in character or it may be slight.

CHART VIb.—QUARTAN FEVER.

The total duration of the paroxysm averages from ten to twelve hours, but may be shorter. Variations are common; the patient may, instead of a chill, experience only a chilly sensation. The most common variation is the occurrence of a hot stage alone or with slight sweating. During the paroxysm the spleen is enlarged and the edge can usually be felt below the costal margin. In the interval or intermission of the paroxysm the patient feels well, and,

unless the disease is unusually severe, he is able to be up. Bronchitis is common and herpes, usually labial, is almost as frequent in malaria as in pneumonia.

(a) *Tertian Fever*.—This type depends upon the presence in the blood of the tertian parasite, an organism usually present in sharply defined groups, whose cycle of development lasts approximately forty-eight hours, segmentation occurring every third day. In infections with one group of tertian parasites the paroxysms occur at remarkably regular intervals of about forty-eight hours, every third day—hence the name *tertian*. Very commonly there are two groups of parasites which reach maturity on alternate days, resulting

CHART VIc.—Æstivo-Autumnal Fever.—Quotidian Paroxysms.

in daily (*quotidian*) paroxysms—*double tertian infection*. In young children the fever may be irregular.

(b) *Quartan Fever*.—The symptoms resemble those of the tertian infection but as a rule are milder. Paroxysms appear on the fourth day and correspond with the evolution of a parasitic cycle of seventy-two hours. In recent infections the recurrence of the paroxysm may be almost precisely the same hour every day. The infection may be double, in which case there are two paroxysms followed by a day of intermission, or *triple*, in which there is a daily paroxysm. As pointed out by the old Greek physicians the quartan infection is difficult to cure. Disappearing for a time spontaneously, or yielding promptly to quinine, it has a singular proneness to relapse, even after the most energetic treatment.

Thus a daily intermittent fever may be due to infection with either tertian or quartan parasites. The *diagnosis* is readily made by blood examination if the patient has not taken quinine, as the parasites are present as a rule at all times.

Course.—After a few paroxysms, or after the disease has persisted for

ten days or two weeks, the patient may get well without any special medication but relapses are common. The infection may persist for years, and an attack may follow an accident, an acute fever, or a surgical operation. A resting stage of the parasite has been suggested in explanation of these long intervals. Persistence of the disease leads to anæmia owing to the destruction of blood cells. Ultimately the condition may become chronic—malarial cachexia.

II. IRREGULAR, REMITTENT, OR CONTINUED FEVERS.—*Æstivo-autumnal Fever*.—This type occurs in temperate climates, chiefly in the later summer and autumn; hence the term *æstivo-autumnal fever*. The severer forms prevail in the southern states and in tropical countries. The *æstivo-autumnal*

CHART VII.—*ÆSTIVO-AUTUMNAL INFECTION*.—REMITTENT FEVER.

The case was treated for a week as one of typhoid fever.

parasite is an organism the length of whose cycle of development, ordinarily about forty-eight hours, is probably subject to considerable variations, while the existence of multiple groups of the parasite, or the absence of arrangement into definite groups, is not infrequent.

The *symptoms* are therefore often irregular. In some instances there may be regular intermittent fever occurring at uncertain intervals of from twenty-four to forty-eight hours, or even more. In the cases with longer remissions the paroxysms are longer. Some of the daily intermittent cases may closely resemble the fever depending upon double tertian or triple quartan infection. Commonly, however, the paroxysms show material differences; their length averages over twenty hours, instead of from ten to twelve; the onset occurs often without chills and even without chilly sensations. The rise in temperature is frequently gradual and slow, instead of sudden, while the fall may occur by lysis instead of by crisis. There may be a marked tendency toward anticipation in the paroxysms, while frequently, from the anticipation of one paroxysm or the retardation of another, more or less continuous fever may result, sometimes without sharp paroxysms. In these cases of continuous and remit-

tent fever the patient has a flushed face and looks ill. The tongue is furred, the pulse is full and bounding but rarely dicrotic. The temperature may range from 102° to 103° , or is in some instances higher. The general appearance is strongly suggestive of typhoid fever—further supported by the splenic enlargement; an initial bronchitis may be present. The course of these cases is variable. The fever may be continuous, with remissions more or less marked; definite paroxysms with or without chills may occur, in which the temperature rises to 105° or 106° F. Intestinal symptoms are usually absent, but a slight jaundice may arise early. Delirium of a mild type may occur. The cases vary greatly in severity; in some instances the condition becomes grave and assumes the pernicious type. It is in this form of malarial fever that so much confusion exists. The similarity to typhoid fever is striking, more particularly the appearance of the facies; the patient *looks* very ill. The cases occur in the autumn when typhoid fever is prevalent. The fever yields, as a rule, to quinine, though cases are met with—rarely indeed in our experience—which are refractory. Several of the charts in Thayer and Hewetson's monograph show how closely the disease may simulate typhoid fever.

The *diagnosis* is definitely made by the examination of the blood. Repeated examinations at short intervals may be required before the parasites are found. The small hyaline forms of the *æstivo-autumnal* parasite are to be found, while, if the course has been over a week, the larger crescentic and ovoid bodies are often seen. The presence of pigmented leucocytes is about as significant as the parasites.

Pernicious Malarial Fever.—This is fortunately rare in temperate climates, and the number of cases is very much less than thirty or forty years ago. Pernicious fever is always associated with the *æstivo-autumnal* parasite. The following are the most important types:

(1) *Comatose Form.*—In this the patient is struck down with symptoms of intense cerebral disturbance, either acute delirium or, more frequently, a rapidly developing coma. A chill may or may not precede the attack. The fever is usually high, and the skin hot and dry. The unconsciousness may persist for from twelve to twenty-four hours, or the patient may sink and die. After regaining consciousness a second attack may prove fatal. In these instances the special localization of the infection is in the brain, where actual thrombi of parasites with marked secondary changes in the surrounding tissues have been found.

(2) *Algid Form.*—In this the attack sets in usually with gastric symptoms; there are vomiting, intense prostration, and feebleness out of all proportion to the local disturbance. The patient complains of feeling cold, although there may be no actual chill. The temperature may be normal, or even subnormal; consciousness may be retained. The pulse is feeble and small, and the respirations are increased. There may be most severe diarrhoea and the urine is often diminished or even suppressed. This condition may persist with slight exacerbations of fever for several days and the patient die in profound asthenia. In the cases with vomiting and diarrhoea the gastro-intestinal mucosa is often the seat of a special invasion by the parasites, thrombosis of the small vessels with superficial ulceration and necrosis occurring.

(3) *Hæmorrhagic Forms*.—Black-water Fever—Hæmoglobinuric Fever—Malarial Hæmoglobinuria.—There are two types of hæmoglobinuria in malaria, the one associated with any severe pernicious attack in which an enormous number of red blood corpuscles are destroyed by parasites, but in the true *black-water fever* there is a solution of red blood corpuscles by an unknown hæmolysin, not directly by the malarial parasites themselves. There are many obscure features connected with black-water fever, especially concerning its etiology. Most authorities consider that malaria is concerned, as the majority of patients have had repeated attacks. Various occurrences may precipitate an attack in a predisposed individual. The taking of quinine is apparently one of these, but quinine is not the cause; it may be a *tertium quid* necessary to produce the hæmolysin. The *symptoms* may come on rapidly with rigors, restlessness, fever, vomiting and marked prostration. There is the passage of dark urine, often scanty, the fever continues and yellow pigmentation appears. In favorable cases after a few days recovery follows. Ominous features are: severe asthenia with syncope, anuria with uræmic manifestations and hyperpyrexia. A rapidly developing severe anæmia may occur. If malarial parasites are present in the blood before the attack they usually disappear during it but return later. The prognosis is always serious.

The figures at Panama, based on five years' work at the Ancon Hospital, given by Deeks and James, show 230 cases in more than 40,000 cases of malaria. Their studies strongly favor the association of black-water fever with malaria, holding that there are three causes superadded to the previous malarial infection: (i) A renewed malarial attack with production of toxins sufficient to destroy many red blood corpuscles; (ii) a lowering of the bodily resistance; (iii) quinine. The general experience at Panama is in favor of withholding quinine in the true erythrolytic hæmoglobinuria.

Malarial Cachexia.—The general symptoms are those of secondary anæmia—breathlessness on exertion, œdema of the ankles, and hæmorrhages, particularly into the retina. Occasionally the bleeding is severe, and fatal hæmatemesis may occur in association with the enlarged spleen. The fever is variable. The temperature may be low for days, not going above 99.5°. In other instances there may be irregular fever, and the temperature rises gradually to 102.5° or 103° F. With careful treatment the outlook is good, and a majority of cases recover. The spleen may reduce in size but it may always remain somewhat enlarged.

Latent Malarial Infection.—There may be parasites in the body without any clinical manifestations of the disease. The parasites are present in the spleen in all the stages of the human cycle.

Rarer Complications.—Paraplegia may be due to a peripheral neuritis or to changes in the cord, and hemiplegia may occur in the pernicious comatose form, or occasionally at the very height of a paroxysm. Acute ataxia has been described, and there are remarkable cases with the symptoms of disseminated sclerosis (Spiller). Multiple gangrene may occur. *Orchitis* has been described. Acute pancreatitis has been reported.

Relapse.—It is not easy to explain the relapse. Some think there is a resting stage of the parasite which remains in the spleen or the bone marrow. Schaudinn believed that there is a special parthenogenetic form which may remain latent for an indefinite period. It may be that parasites are present

but not in sufficient numbers to cause symptoms. Years may elapse between the primary infection and a relapse occurring under conditions that preclude the possibility of re-infection.

Prognosis.—This is good as regards life except in the cases of pernicious malaria in which much depends on prompt recognition and treatment. As to complete killing of all parasites much depends on perseverance in treatment. Complete cure of the æstivo-autumnal forms is often difficult.

Diagnosis.—The endemic index of a country may be determined by the “parasite rate” or by the “spleen rate.” It is best sought for in children, in whom the infection may occur without much disturbance of the health. To determine the index by examining the blood for the parasites is a laborious task; on the other hand, as the work of Ross has shown, the index may be readily gauged by an examination of the spleen. Thus, in Mauritius, of 31,022 children, 34.1 per cent. had enlarged spleen. In Bombay, among 50,000 children examined, the spleen index varied from 5.3 per cent. in the Hindoos to 23.2 per cent. in the Parsees (Bentley).

The individual forms of malarial infection are readily recognized by examination of the fresh or stained film, but it requires a long and careful training to become an expert in blood examination. Great progress has been made and a diagnosis of malaria is no longer a refuge for our ignorance. One lesson it is hard for the practitioner to learn—namely, that an intermittent fever which resists quinine is not malarial.

The malarial poison is supposed to influence many affections in a remarkable way, giving to them a paroxysmal character. A whole series of minor ailments and some more severe ones, such as neuralgia, are attributed to certain occult effects of malaria. The more closely such cases are investigated the less definite appears the connection with malaria.

Prophylaxis.—In the discovery of Laveran there lay the promise of benefits more potent than any gift science had ever offered to mankind—viz., the possibility of the extermination of malaria. By the persistent efforts of Ross this promise has reached the stage of practical fulfilment, and one of the greatest scourges of the race is now under our command. The story of the Canal Zone, Panama, under Gorgas is a triumph of the application of scientific methods. Between 1881 and 1904 among the employees of the French Canal Company (a maximum in 1887 of 17,995, of whom 15,726 were negroes) the monthly mortality ranged from 60 to 70, and on seven occasions was above 100, once reaching the enormous figure of 176.97 per 1,000. With the measures given below, the mortality has fallen below that of temperate regions. For the year 1910 the death rate from disease was 7.5 per 1,000.

This most successful campaign has been carried out on the following lines:

(1) The eradication of mosquito propagation areas by drainage, and the filling of places where the larvæ exist. This has been done in large districts.

(2) The control of propagation areas that are allowed to exist or that cannot be economically and permanently treated. On small areas the larvæ are prevented from arriving at the adult stage by the use of crude oil or kerosene, and in large bodies of water by treating the edges where alone the mosquito larvæ exist. A concentrated larvacide of carbolic acid, resin and caustic soda has been found effective, when applied to the edges of large pools, ditches,

wet areas and streams. A barrel of oil with an automatic drip at the head of a stream has been found to work satisfactorily.

(3) Protection by *screening* of houses. Copper-bronze screens of 18 mesh to the inch are effective. Cotton bar treated with wax is recommended as inexpensive. Screened vestibules decrease the chance of access of mosquitoes. Mosquito nets over the beds are found, as a rule, to be a failure, chiefly because few persons sleep through a whole night without an arm or leg coming in contact with the netting on which the anopheles settle.

(4) The *destruction* of adult anopheles. In rooms the mosquitoes are usually in the corners, and very often within a foot of the floor.

Of the enormous importance of these anti-malarial measures there can be no question. It requires system, organization, energy and perseverance. But the story of Havana, the story of Ismailia, and, above all, the story of the Panama Canal Zone show what can be done. The following chart, taken

CHART VII.—MALARIA CASES AMONG THE EMPLOYEES OF THE ISTHMIAN CANAL COMMISSION, 1906-1910.

from an article of Le Prince, the chief sanitary inspector of the Zone, gives a good idea of the results. The objection offered on the score of cost in the tropics has been shown by Gorgas to be fallacious.

Individual.—Every patient with malaria should be regarded as a source of infection (a *carrier*). In the tropics segregation of Europeans may do much to lessen the chances of infection. Every patient should receive thorough and prolonged treatment with quinine. There is far too much carelessness on this point in the profession. Malarial infection is difficult to eradicate. Quinine is the only known drug which is an effective parasiticide. Patients should resume treatment in the spring and autumn for several years after the primary infection. In very malarial districts, as many persons harbor the

parasites who do not show any (or at the most very few) signs, a systematic treatment with quinine is important, particularly in young children.

Patients with the disease should be protected from mosquitoes as far as possible. As a rule, anopheles are more likely to bite after sundown, so that in regions in which the disease prevails extensively screening should be used. Persons going to a malarial region should take 5 grains (0.3 gm.) of quinine daily and a double dose once a week.

Treatment.—The patient should be in bed and given liquid or soft diet. The bowels should be moved freely, for which a calomel and saline purge is best. In *quinine* we possess a specific remedy and the parasites are most easily destroyed at the stage when they are free in the circulation—that is, during and just after segmentation. While in most instances the parasites of the tertian and quartan forms may be destroyed fairly rapidly, in æstivo-autumnal fever this is much more difficult. If the patient comes under observation shortly before an expected paroxysm, the immediate administration of quinine gives a maximum effect upon the group of parasites. The quinine will not prevent the paroxysm, but will destroy the greater part of the group of organisms and prevent its recurrence. In general the best method is to give quinine regularly without special reference to the paroxysms. Small doses may be sufficient to stop the paroxysms but the object is to kill all the parasites. A safe dosage is 30 grains (2 gm.) a day for two to three weeks, 20 grains (1.3 gm.) daily for a month and 10 grains (0.6 gm.) daily for two months. The taking of quinine *every day* is important. In æstivo-autumnal fever larger doses may be necessary, though in relatively few instances is it necessary to give more than 30 grains (2 gm.) in the twenty-four hours. It is wise to take a course of quinine (10 grains—0.6 gm.—daily for three weeks) twice a year for three years after an attack. During the paroxysm the patient should, in the cold stage, be wrapped in blankets and given hot drinks. The reactionary fever is rarely dangerous and sponging gives comfort.

The quinine should be given in solution or capsules. Pills and compressed tablets may not be dissolved. The use of dilute hydrobromic acid to dissolve the quinine often prevents ringing in the ears. Euquinine, in the same dosage, or quinine tannate, double the amount, may be given to patients with whom quinine disagrees. Plasmochin (a quinoline derivative) is used, especially to kill the sexual forms, in a daily dosage of gr. 1½ (0.1 gm.) for periods of 5 to 7 days. It may be given with quinine.

In cases of æstivo-autumnal fever with *pernicious* symptoms it is necessary to introduce the quinine as rapidly as possible. In these instances the drug should be administered by injection into the muscles, as the dihydrochloride in 10-grain (0.6 gm.) doses, in a freshly prepared solution (1 to 2) in sterile water and repeated in two hours. Further administration must be decided by the condition. The muriate of quinine and urea may also be given intramuscularly in 10-grain (0.6 gm.) doses. In the most severe instances the intravenous administration of quinine is advisable but it is not without danger. Fifteen grains (1 gm.) of the bimuriate with 40 grains (2.6 gm.) of sodium chloride may be injected in ten ounces (300 c. c.) of freshly distilled water, or the same amount of the dihydrochloride in 500 c. c. of saline solution. For extreme restlessness in these cases opium is indicated, and cardiac stimulants may be necessary. If in the comatose form

the internal temperature is raised, the patient should be sponged or given a tub bath. For malarial anæmia iron and arsenic are indicated.

In *hæmoglobinuria* if the blood shows parasites quinine should be administered cautiously in small doses. In the post-malarial forms quinine aggravates the attack. Absolute rest is essential; fluid should be given freely, by bowel or intravenously if necessary. Stimulation may be necessary. In malarial *cachexia* the patient should have a change of climate, be given a liberal diet, and take quinine in small doses with iron and arsenic for some time.

IV. TRYPANOSOMIASIS

Definition.—A chronic disorder characterized by fever, lassitude, weakness, wasting, and often a protracted lethargy—sleeping sickness. *Trypanosoma gambiense* and *T. rhodesiense* are the active agents in the disease in Africa and *T. cruzi* in South America.

Trypanosomes are flagellate infusoria, parasitic in a great many invertebrate and vertebras. The life history is in two stages, a flagellate monadine phase, in which they live in the blood stream of vertebrates and in some of which they cause serious disease; the other is a gregarine non-flagellate phase which may also be parasitic and which is met with in forms of kala-azar.

History.—In 1843 Gruby found a blood parasite in the frog which he called *Trypanosoma sanguinis*. Subsequently it was found to be a common blood parasite in fishes and birds. In 1878 Lewis found it in the rat—*T. lewisi*—in which it apparently does no harm. The pathological significance was first suggested in 1880 by Griffith Evans, who discovered *trypanosomes*—*T. evansi*—in the disease of horses and cattle in India known as *surra*. In 1895 Bruce made the important announcement that the tsetse fly disease or *nagana* of South Africa, which made whole districts impassable for cattle and horses, was really due to a trypanosome—*T. brucei*. Normally present in the blood of the big-game animals of the districts, it was conveyed by the tsetse fly to the non-immune horses and cattle imported into what were called the fly belts. Other trypanosomes are *T. cruzi* (Brazil), the Philippine *surra*, studied by Musgrave, the *mal de caderas*—*T. equinum*—of South America and a harmless infection in cattle in the Transvaal caused by *T. theileri*.

Human Trypanosomiasis.—In 1901 Dutton found a trypanosome in the blood of a West Indian. In 1903 Castellani found trypanosomes in the cerebro-spinal fluid and blood of five cases of African sleeping sickness. The Royal Society Commission (Bruce and Nabarro) demonstrated the frequency of the parasites in the cerebro-spinal fluid and blood in sleeping sickness, and suggested that it was a sort of human tsetse fly infection.

DISTRIBUTION.—For many years it had been known that the West African natives were subject to a remarkable malady known as the lethargy or sleeping sickness. It was also met with among the slaves imported into America. The disease prevails in Gambia, Sierra Leone, and Liberia, and has spread rapidly in the Congo basin, Uganda, and Rhodesia. The opening up of equatorial Africa has led to intercommunication between districts which were formerly isolated, and the seriousness of the disease may be appreciated from

the fact that within three years after its introduction 100,000 negroes died of it in Uganda. In the infected regions a large number of natives, not apparently suffering from the disease, harbor the parasites in the blood and suffer only with occasional attacks of fever, during which the trypanosomes are also found in the cerebro-spinal fluid. Persons particularly prone are those who live on the wooded shores of the lakes and rivers, such as fishermen and canoe men.

The *T. gambiense* is introduced by the bite of a fly, the *Glossina palpalis*, and *T. rhodesiense* and *T. brucei* by *Glossina morsitans*. The fly lives on the bushes on the lake shores or river banks, and feeds on the blood of crocodiles, antelopes, etc. The trypanosomes undergo changes in the body of the fly and the infectivity does not appear until the thirty-second day, but continues for at least 75 days (Bruce).

Symptoms.—There may be a long latent period in natives. The Uganda Commissioners divide the course of the disease into three stages: first, of fever with rapid pulse, dulling of the mind, and loss of weight; secondly, the stage of tremors in which the gait becomes shuffling, the speech slow, and there are tremors of the tongue and of the hands and feet; lastly, a stage in which the patient becomes lethargic with low temperature and presents the typical picture of sleeping sickness. The parasites are found in the cerebro-spinal fluid, less constantly in the blood. In the early stages the glands of the neck are involved, and Todd and Dutton recommend puncture of these glands for the purpose of diagnosis. Death is usually caused by some intercurrent infection, as purulent meningitis or suppuration of the lymph-glands. The duration is seldom longer than eighteen months. To stay the ravages and prevent the spread of the disease will tax the energies of the nations interested in the settlement of tropical Africa. The hope appears to be in the extermination of the animals upon which the *Glossina palpalis* feeds, just as the killing off of the big game in other parts of Africa has saved the cattle from the ravages of the tsetse fly. Though a colossal task, the examination of natives of infected districts should be undertaken, isolation villages established, and the cases kept under observation and treatment.

The South American form (*T. cruzi*) occurs chiefly in Brazil (sometimes termed Chagas' disease). The parasites are found in the peripheral blood for a short time only: in the organs they assume a form like Leishmania. The clinical features are varied; acute forms occur especially in children, in some showing involvement of the nervous system, which is usually fatal, in others the main effect is insufficiency of the endocrine glands, especially the thyroid. The more chronic forms show features due particularly to hypothyroidism, cardiac disease, and varied nervous phenomena—paralyses, idiocy, etc.

Diagnosis.—The trypanosomes may be found in the blood or by puncture of the enlarged glands. In the "sleeping sickness stage" they are found almost always in the cerebro-spinal fluid. Inoculation of blood into guinea-pigs and the complement fixation test are important aids.

Prognosis.—A few cases in Europeans have been cured, and some of these have been without symptoms for a number of years. The criteria of cure are the absence of symptoms, failure to find the trypanosomes, and negative inoculation of the blood into susceptible animals. The outlook is hopeless in the stage of sleeping sickness.

Treatment.—Atoxyl introduced by Wolferstan Thomas and Breinl appears to have given good results. Antimony has been effectual. Potassium or sodium antimony tartrate is given intravenously twice a week. The first dose is gr. $\frac{1}{2}$ (0.03 gm.), increased to gr. iii (0.12 gm.). A total amount of 30 to 40 grains is given. Tryparsamide has a marked effect on *T. gambiense*. It is best given intramuscularly in single doses of 0.5-3 gm. Visual disturbance is apparently due to too frequent administration. The remedy, "Bayer 205," has given good results. Etharsanol and proparsanol are promising newer remedies.

V. LEISHMANIASES

Definition.—Under this designation there are two main forms of disease: one is a general infection (Indian Leishmaniasis or Kala-azar and infantile Kala-azar); the other presents cutaneous lesions (tropical or oriental sore in the East and the cutaneous Leishmaniasis of tropical America).

Indian Kala-Azar.—This is characterized by enlargement of the spleen and liver, anæmia, irregularly remittent fever and marked emaciation. Leishman, in 1900, discovered the parasite which was subsequently studied by Donovan (*Leishmania donovani*).

Pathology.—The *Leishmania* bodies are distributed throughout, especially as intracellular parasites of the endothelial cells. The largest numbers are in the liver, spleen and bone marrow. Ulcers in both the small and large intestine are found. The intestinal villi are enlarged and contain large numbers of the parasites especially in the endothelial cells.

Etiology.—The method of transmission is not settled. Proof of transmission by bed-bugs and fleas is lacking. A variety of sand fly (*Phlebotomus*) may be responsible. Dogs and monkeys can be inoculated with the parasite which is an oat-shaped body 2 to 4 μ long by 1 to 2 μ broad, containing two chromatin bodies. It can be cultivated outside the body.

Symptoms.—The onset is with remittent fever and enlargement of the liver and spleen. Anæmia is marked with hæmorrhages and progressive emaciation. A curious pigmentation appears, from which the name black-fever. Diarrhœa and dysentery are not infrequent. The hæmoglobin and red cells are reduced to about half the normal figures. Leucopenia is marked; often the white cells number 2,000. Parasites may be found in the leucocytes. The course of the disease without treatment varies from some months to two years. The *diagnosis* is made by finding the parasite which occurs in the peripheral blood in a large percentage of cases. The blood may be citrated and after centrifugalization the contents of the bottom of the tube examined. Splenic puncture may be done.

Treatment.—Antimony has almost a specific effect, especially if given early. Potassium or sodium antimony tartrate twice a week intravenously is given in 1 or 2 per cent. solution, freshly prepared. The first dose is one-half grain (0.03 gm.) gradually increased to gr. ii or iii (0.13-0.2 gm.), until gr. xxx (2 gm.) have been given.

Infantile Kala-Azar.—This form is the infantile splenic anæmia long recognized in the countries of the Mediterranean basin formerly thought to be due to *L. infantum* but now regarded as due to *L. donovani*. The clinical fea-

tures are much like those of the disease in adults. The disease may be reproduced in dogs and monkeys and an infection of dogs exists in the endemic areas of infantile kala-azar but it does not seem probable that the disease is transmitted by the dog flea.

Tropical Sore.—(Aleppo Boil, Delhi Boil, Oriental Sore, Bagdad Sore, etc.). Under various names is described a form of Leishmaniasis characterized by a granuloma of the skin which may ulcerate or not and is usually on exposed parts. The parasite (*Leishmania tropica*) was discovered by Homer Wright. This occurs widely distributed in the East; imported cases are occasionally seen in the United States. The first lesion is a papule which extends and may ulcerate. The ulcer somewhat resembles a gumma. The course, if the disease is untreated, is self-limited with a period of six to eighteen months. Marked scars are left. The *diagnosis* is made by finding the parasite, usually in the margin of an ulcer, or in blood cultures taken from the site of the lesion. The *treatment* is the same as for kala-azar or by the application of a 2 per cent. antimony ointment. Inoculation has been done as immunity usually follows the healing of the lesion.

The American form occurs in Central and South America and is due to *L. braziliensis*. In its general features it is much like the previous form but may involve the mucous membrane of the nose and mouth. The lymph nodes are often affected. The treatment is the same.

VI. THE RELAPSING FEVERS

Definition.—A group of specific infections caused by spirochaetes, characterized by febrile paroxysms which usually last five or six days with remissions of about the same length of time. The paroxysms may be repeated three or even four times, whence the name relapsing, or recurring, fever. European Indian, American and African forms are described presenting clinically much the same features, but the parasites differ. The organism varies somewhat in different countries and various insects (lice, bugs and ticks) are concerned in its transmission.

Etiology.—The European form, also known as “famine fever” and “seven-day fever,” has been known since the early part of the eighteenth century, and has at times prevailed extensively especially in Ireland. It is a very rare disease in England. In the United States the disease appeared in 1844, when cases were admitted to the Philadelphia Hospital, which are described by Meredith Clymer in his work on Fevers. Flint saw cases in 1850-’51. In 1869 it prevailed extensively in epidemic form in New York and Philadelphia; since when it has not reappeared. The European form is due to *Spirochæta recurrentis* (formerly *Spirillum obermeieri*) transmitted by lice and bed-bugs: the American form is due to *S. novyi*; the Asiatic form to *S. carteri*; and the Persian form to *S. persica*.

The *Central African relapsing fever*, known as *tick fever*, is a serious and widespread affection, the parasite of which is *S. duttoni*. It is transmitted by the tick *Ornithodoros moubata*, but as Leishman has shown, not by direct inoculation with the salivary secretion, but from other secretions voided in the act of gorging. The symptoms are similar to those of European relaps-

ing fever, and from five to seven relapses may take place. The mortality is not very high. The North African form is due to *S. berbera* and is transmitted by lice.

The spirochæte, described by Obermeier in 1873, was one of the first organisms shown to be definitely associated with a specific fever. It is from 15 to 40 μ in length, spirally arranged like a corkscrew, sometimes curved and twisted. It is actively motile, and it is present in the blood during the febrile paroxysm, disappearing at intervals. Plotz reported the cultivation of the spirochætes directly from the blood. The mode of transmission is through lice, ticks and bed-bugs, not by direct inoculation but by infection through the insect bite or by scratching, the material being rubbed into the wound. The special conditions under which it occurs are similar to those of typhus fever. Neither age, sex, nor season seems to have any special influence. One attack does not confer immunity, but later infections may be milder and with one febrile period only or with few symptoms.

Morbid Anatomy.—There are no characteristic anatomical appearances in relapsing fever. If death takes place during the paroxysm the spleen is large and soft, and the liver, kidneys and heart show cloudy swelling. There may be infarcts in the kidneys and spleen. The bone-marrow has been found in a condition of hyperplasia. Ecchymoses are not uncommon.

Symptoms.—The *incubation* appears to be short; in some instances the attack occurs within twelve hours after exposure; more frequently, however, from five to seven days elapse.

The *invasion* is abrupt, with chill, fever, and intense pain in the back and limbs. In young persons there may be nausea, vomiting, and convulsions. The temperature rises rapidly and may reach 104° on the evening of the first day. Sweats are common. The pulse is rapid, ranging from 110 to 130. There may be delirium if the fever is high. Swelling of the spleen can be detected early. Jaundice is common in some epidemics. The gastric symptoms may be severe, but intestinal symptoms are rare. Cough may be present. Occasionally herpes is noted, and there may be miliary vesicles and petechiæ. During the paroxysm the blood invariably shows the spirochætes and there is usually a leucocytosis. After the fever has persisted with severity or even with an increasing intensity for five or six days the crisis occurs. In the course of a few hours, accompanied by profuse sweating, sometimes by diarrhœa, the temperature falls to normal or even subnormal.

The crisis may occur as early as the third day or may be delayed to the tenth; it usually comes, however, about the end of the first week. In delicate and elderly persons there may be collapse. The convalescence is rapid, and in a few days the patient is up and about. Then in a week, usually on the fourteenth day, he again has a rigor, or a series of chills; the fever returns and the attack is repeated. A second crisis occurs from the twentieth to the twenty-third day, and again the patient recovers rapidly. As a rule, the relapse is shorter than the original attack. A second and a third may occur, and even a fourth and a fifth. The number varies in the different forms; there is usually one in the American form. In epidemics there are cases which terminate by crisis on the seventh or eighth day without the occurrence of relapse. In protracted cases the convalescence is very tedious, as the patient is much exhausted.

Relapsing fever is not a very fatal disease. Murchison put the mortality

Relapsing fever is not a very fatal disease. The mortality is usually from 2 to 5 per cent., but it has been as high as 30 per cent. in India. In the enfeebled and old, death may occur at the height of the first paroxysm.

Complications are not frequent. In some epidemics hæmatemesis and hæmaturia have occurred. Pneumonia is not infrequent. The acute enlargement of the spleen may end in rupture. Post-febrile paralyses may occur. Ophthalmia has followed in certain epidemics, and may prove a very tedious and serious complication. In pregnant women abortion usually takes place.

CHART VIII.—RELAPSING FEVER (Murchison).

Convulsions occasionally follow. Dutton, the well-known worker on tropical diseases, died in *status epilepticus* some weeks after the attack.

Diagnosis.—The onset and general symptoms at first may not be distinctive. At the beginning of an epidemic the cases are usually regarded as anomalous typhoid; but once the typical course is followed the diagnosis is clear. The blood examination is distinctive during the febrile period.

Prophylaxis.—This is concerned with the avoidance of insects which carry the infection; measures to exterminate them and to prevent them from gaining access to sick and well are in order. In the African form avoidance of infected huts is essential.

Treatment.—The disease should be treated like any other continued fever, by careful nursing, a regular diet, and ordinary hygienic measures. One dose of arsphenamine has usually proved efficient. Pain in the back, limbs and joints may require sedatives. In enfeebled persons the collapse at the crisis may be serious, and ammonia and digitalis should be given freely.

VII. YELLOW FEVER

Definition.—A fever of tropical and subtropical countries, characterized by a toxæmia of varying intensity, with jaundice, albuminuria, and a marked tendency to hæmorrhage, especially from the stomach, causing the “black vomit.” The disease is transmitted through the bite of a mosquito, the *Aedes aegypti* (*Stegomyia calopus*).

Etiology.—The disease prevails endemically in certain sections of the Spanish Main. Until recently it has existed in Cuba. From these regions

it occasionally extended and prevailed epidemically in the southern states. Now and then it was brought to the large seaports of the Atlantic coast. Formerly it occurred extensively in the United States. In the latter part of the eighteenth century and the beginning of the nineteenth frightful epidemics prevailed in Philadelphia and other northern cities. The epidemic of 1793, in Philadelphia, so graphically described by Matthew Carey, was the most serious that has ever visited any city of the middle states. The mortality, as given by Carey, from August to November, was 4,041, of whom 3,435 died in September and October. The population of the city at the time was only 40,000. Epidemics occurred in the United States in 1797, 1798, 1799, and in 1802, when the disease prevailed slightly in Boston and extensively in Baltimore. In 1803 and 1805 it again appeared; then for many years the outbreaks were slight and localized. In 1853 the disease raged throughout the southern states. There were moderately severe epidemics in 1867, 1873, and 1878, and milder ones in 1897, 1898, and 1899. In September, 1903, yellow fever became epidemic along the Mexican side of the Rio Grande. It crossed into Texas and prevailed in several border towns. In Laredo there were 1,014 cases, with 107 deaths. The efficient work of the public health service is shown by the differences between New Laredo on the Mexican border, just across the river, where 50 per cent. of the population contracted the disease, and Laredo, Texas, in which only 10 per cent. of a population of 10,000 were attacked. In Europe it has occasionally gained a foothold, but there have been no widespread epidemics. It is sometimes carried to ports in Great Britain and France, but it has never extended into these countries. As Ross points out, yellow fever is a disease in which the parasites live a short time in the human host, unlike malaria. The infective period in a case lasts only about three days, so that, unless the stegomyia index is high, the disease has no chance to reach epidemic form. The epidemics in the United States have always been in the summer and autumn months, disappearing rapidly with the onset of cold weather.

Mode of Transmission.—No belief was more strong among the laity than that the disease is transmitted by infected clothing, and quarantine efforts were chiefly directed to the disinfection of articles of all sorts shipped from infected ports. The experiments carried out by the Yellow Fever Commission of the United States Army, consisting of Drs. Walter Reed, Carroll, Lazear, and Agramonte, demonstrated conclusively that the disease cannot be conveyed in this way. At Camp Lazear, Cuba, a frame house was so constructed as to shut out the sunlight and fresh air, and the vestibule was thoroughly screened. The average temperature for sixty-three days was kept about 76° F. Boxes filled with sheets, pillow-slips, blankets, etc., contaminated by contact with cases of yellow fever and the discharges were placed in the house. Dr. R. P. Cooke and two privates of the hospital corps, all non-immunes, entered this building and for twenty days occupied the room, each morning packing the infected articles in the boxes and at night unpacking them. In their experiments, seven non-immune subjects during a period of sixty-three days lived in contact with the fomites and remained perfectly well. These experiments, conducted in the most rigid scientific manner, completely discredited the belief in the transmission of the disease by fomites.

We must bear testimony to the heroism of the young soldiers who volun-

tarily, without compensation and purely in the interests of humanity, submitted to the experiments, and also to the zeal with which members of our profession, at great personal risk, attempted to solve the riddle of this most serious disease. The deaths of Lazear, Myers, Noguchi, Stokes, Young and Lewis from yellow fever have added their names to the already long roll of the martyrs of science.

Stimulated by the work of Ross on malaria, the American Commission demonstrated conclusively that yellow fever is transferred by a mosquito, *Aedes aegypti*, previously fed on the blood of infected persons. The Commission showed also that in non-immunes the disease could be produced by either the subcutaneous or the intravenous injection of blood taken from patients suffering with the disease.

An interval of about twelve days or more after biting the patient appears to be necessary before the mosquito is capable of transmitting the disease. As Reed pointed out, the mosquito theory fits in with well-recognized facts in connection with the epidemics. After the importation of a case into an uninfected region, a definite period elapses, rarely less than two weeks, before a second case occurs. The disease prevails most during the mosquito season, and disappears with the appearance of frost. Probably, the disease is kept up by its prevalence in a very mild form among children. In all probability the immunity which is acquired by prolonged residence in a locality in which the disease is endemic is due to the occurrence of very slight attacks. One attack does not always confer immunity. Rosenau reports two attacks within eight years, and Libby two attacks within a period of two years.

The cause of yellow fever is unknown but it is probably a filterable virus. The disease can be transmitted to certain *Macacus* monkeys. Convalescent serum protects the monkeys against infection. The virus is present in the blood of a patient with yellow fever on the second and third day of the disease. A mosquito when infected by biting the patient probably remains so for the duration of its life, which may be as long as sixty days.

Morbid Anatomy.—The skin is more or less jaundiced, even though the patient did not appear yellow before death. Cutaneous hæmorrhages may be present. Degenerative changes in the capillary endothelial cells cause the hæmorrhages. The heart may show fatty change; the stomach presents more or less hyperæmia of the mucosa with petechiæ. There is often general glandular enlargement; the cervical, axillary and mesenteric groups are most involved. The liver is usually of a pale yellow or brownish-yellow color, and the cells are in various stages of a fatty degeneration. From the date of Louis' observations at Gibraltar in 1828, the appearances of this organ have been very carefully studied. Hæmorrhagic and necrotic areas are common. The toxin has a selective degenerative effect on the liver cells without any inflammatory process. The kidneys show acute parenchymatous inflammation. The epithelium of the convoluted tubules is swollen and very granular; there may also be necrotic changes. The spleen is not enlarged but there is degeneration of its endothelial cells. The adrenal glands may show fatty degeneration. Hæmorrhages may be found in the serous membranes, as the pleura, and in the meninges. None of the lesions can be regarded as absolutely specific. The general character of the pathological changes suggests the effect of toxins rather than acute inflammatory lesions.

Symptoms.—The incubation is usually three or four days; in 13 experimental cases it ranged from forty-one hours to five days, seventeen hours. The onset is sudden, as a rule, without premonitory symptoms, and in the early hours of the morning. Chilly feelings are common, and are usually associated with headache and very severe pains in the back and limbs. The fever rises rapidly and the skin feels very hot and dry. The tongue is furred, but moist; the throat sore. Nausea and vomiting are not constant, and become more intense on the second or third day. The bowels are usually constipated. The following in detail, are the more important characteristics:

FACIES.—Even as early as the first morning the patient may present a characteristic facies, one of the three distinguishing features of the disease, which Guitéras describes as follows: The face is flushed, more so than in any other acute infectious disease at such an early period. The eyes are injected, the color is a bright red, and there may be a slight tumefaction of the eyelids and of the lips. Even at this early date there is to be noticed in connection with the injection of the superficial capillaries of the face and conjunctivæ a slight icteroid tint, and “the early manifestation of jaundice is undoubtedly the most characteristic feature of the facies of yellow fever.”

THE FEVER.—On the morning of the first day the temperature may range from 100° to 106° F., usually it is between 102° and 103° F. During the evening of the first day and the morning of the second day the temperature keeps about the same. There is a slight diurnal variation on the second and third day. In very mild cases the fever may fall on the evening of the second or on the morning of the third day, or in abortive cases even at the end of twenty-four hours. In cases that are to terminate favorably the defervescence takes place by lysis during a period of two or three days. The remission or stage of *calm*, as it has been called, is succeeded by a febrile reaction or secondary fever, which lasts one, two, or three days, and in favorable cases falls by a short lysis. On the other hand, in fatal cases the temperature is continuous, becomes higher than in the initial fever, and death follows shortly.

THE PULSE.—On the first day the pulse is rarely more than 100 or 110. On the second or third day, while the fever still keeps up, the pulse begins to fall, as much perhaps as 20 beats, while the temperature has risen 1.5° or 2°. On the evening of the third day there may be a temperature range of 103° and a pulse of only 75, or “a temperature between 103° and 104° with a pulse running from 70 to 80.” This important diagnostic feature was first described by Faget, of New Orleans. During defervescence the pulse may become still lower, down to 50, 48, or 45, or even as low as 30; a slow pulse at this period is not the special circulatory feature of the disease, but *the slowing of the pulse with a steady or even rising temperature.*

ALBUMINURIA.—This, the third characteristic feature, occurs as early as the evening of the third day. Guitéras says very truly that it is very rare so early in other fevers except those of an unusually severe type. “Even in the mild cases that do not go to bed—cases of ‘walking yellow fever’—on the second, third, or fourth day of the disease albuminuria will show itself.” It may be quite transient. In the severer cases the amount of albumin is large, and there may be numerous casts and all the signs of an acute nephritis; or complete suppression may supervene, and death occurs in uræmic convulsions or coma within twenty-four or thirty-six hours.

GASTRIC FEATURES.—“*Black Vomit.*”—Irritability of the stomach is present from the outset, and the vomited matter consists of the contents of the stomach, and subsequently of mucus and a grayish fluid. In the third stage the vomiting becomes more pronounced and in the severe cases is characterized by the presence of blood. It may be copious and forcible, producing much pain in the abdomen and along the gullet. There is nothing specific in this “black vomit,” which consists of altered blood, and it is not necessarily a fatal symptom, though occurring only in the severer attacks. Other hæmorrhagic features may be present—petechiæ on the skin and bleeding from the gums or from other mucous membranes. The bowels are usually constipated, the stools not clay-colored, except late in the disease. They are sometimes tarry from the presence of altered blood.

MENTAL FEATURES.—In very severe cases the onset may be with active delirium. “As a rule, in a majority of cases, even when there is black vomit, there is a peculiar alertness; the patient watches everything going on about him with a peculiar intensity and liveliness” (Guitéras).

Relapses occasionally occur. Among the varieties of the disease it is important to recognize the mild cases, characterized by slight fever, continuing for one or two days, and succeeded by a rapid convalescence. In the absence of a prevailing epidemic they would scarcely be recognized as yellow fever. Cases of greater severity have high fever and the features of the disease are well marked—vomiting, extreme prostration, and hæmorrhages. And, lastly, in the malignant form the patient is overwhelmed by the intensity of the fever, and death takes place in two or three days.

In severe cases convalescence may be complicated by parotitis, abscesses in various parts of the body, and diarrhœa.

Diagnosis.—(a) **FROM DENGUE.**—The difficulty in the differential diagnosis of these two diseases may lie in their coexistence, as during 1897 in parts of the southern states. During the autumn of 1897 the profession of Texas was divided on the question of the existence of yellow fever in the State; some claiming that the disease was dengue, others including Guitéras and West, that yellow fever also existed. In a majority of the cases the three diagnostic points upon which Guitéras lays stress—the facies, the albuminuria, and the slowing of the pulse with maintenance or elevation of the fever—are sufficient for the diagnosis. He states, too, that jaundice, which does sometimes occur in dengue, rarely appears as early as the second or third day of the disease, and on this much stress should be laid. Hæmorrhages are much less common in dengue, but they do occur. There is a marked leucopenia in dengue.

(b) **FROM MALARIAL FEVER.**—In the early stages of an epidemic cases may be mistaken for malarial fever. In the southern states the outbreaks have usually been in the late summer months, the season in which æstivo-autumnal fever prevails. Among the points to be specially noted is the absence of early jaundice. Even in the most intense types of malarial infection the color of the skin is rarely changed within four or five days. To the experienced eye the facies would be of considerable help if the case was seen from the outset. Albumin is rarely present in the urine so early as the second day in a malarial infection. Other important points are the swelling of the spleen in malaria, while in yellow fever it is not much enlarged.

Hæmorrhages, and particularly the black vomit, epistaxis, and bleeding gums are very rare in malaria. In the so-called hæmorrhagic malarial fever the patient has usually had previous attacks of malaria. Hæmaturia is a prominent feature, while in yellow fever it is by no means frequent. The point of greatest importance is the finding of malarial parasites.

Spirochætal jaundice may cause difficulty. The injection of some of the patient's blood intraperitoneally into a guinea-pig causes a marked infection in this disease; nothing results in yellow fever.

Prognosis.—In its graver forms yellow fever is one of the most fatal of epidemic diseases. The mortality has ranged, in various epidemics, from 15 to 85 per cent. In heavy drinkers and those who have been exposed to hardships the death-rate is much higher than among the better classes. In the epidemic of 1878, in New Orleans, while the mortality in hospitals was over 50 per cent. of the white and 21 per cent. of the colored patients, in private practice it was not more than 10 per cent. among the white patients.

Prophylaxis.—The clearing of Havana by Gorgas was a direct outcome of the work of Reed and his colleagues. The city had been infected continuously for 130 years. Non-immunes came in at the rate of 20,000 a year, and there were 6,000 children born. The city was divided into districts, each under an inspector, whose duty was: (1) To prevent the breeding of *stegomyia* mosquitoes. (2) To destroy those that had become infected. (3) To prevent mosquitoes becoming infected by protecting the sick so that they could not be bitten by mosquitoes. The work was begun in February, 1901, and the last case of yellow fever occurred in September of that year, since which date, with the exception of a slight return, the city has been free. At Panama, a serious problem was how to fight yellow fever. Conditions were such that it took sixteen months before the disease disappeared. There has been no return. In the yellow fever wards at Ancon during 1905 all the physicians and nurses were non-immune, but not one contracted the disease, as the wards were so screened that no *stegomyia* mosquitoes could get at the patients. If the patient is protected from mosquitoes for the first three days of the attack infection is prevented.

Treatment.—The patient should be at rest in bed and for the first few days the diet should consist of very simple fluids. Elimination is an important part of treatment. Water should be given as freely as possible, best in the form of cold carbonated alkaline water. The bowels should be opened by a calomel and saline purge and enemata used if necessary. If there is vomiting, fluid should be given by the bowel or subcutaneously. Ice in small quantities or cocaine (gr. $\frac{1}{4}$, 0.016 gm.) may be tried. The fever should be treated by hydrotherapy, sponges, packs or baths being used. The alkaline treatment is favorably regarded, sodium bicarbonate in full doses being given at short intervals and as much alkaline water as possible. Uræmic symptoms are best treated by the hot baths or packs, the free administration of fluid and hot bowel irrigations. Stimulants, especially strychnine, should be used during the second stage when the heart becomes feeble and rapid.

VIII. SYPHILIS

I. HISTORY, ETIOLOGY AND MORBID ANATOMY

Definition.—A specific disease of slow evolution caused by *Treponema pallidum* (*Spirochæta pallida*) propagated by inoculation (acquired syphilis) or transmission through the mother (congenital syphilis).

History.—Whether the disease was known in Europe before 1493 is still discussed. Bloch, in the *System of Syphilis*, Vol. I, 1908, insists that there is no evidence of pre-Columbian syphilis in the Eastern hemisphere before the return of the Spanish sailors from Hayti from whom it spread among the inhabitants of Barcelona. In 1493 it reached Italy with the army of Charles VIII. His soldiers syphilized Naples; the disease spread throughout Italy, and in a few years Europe was aflame. On the other hand, writers who contend for the antiquity of the disease in Asia and Europe rely on certain old Chinese records, on references in the Bible and in old medical writers to diseases resembling syphilis and on suggestive bone lesions in very old skeletons. The balance of evidence, according to the best syphilographers, is in favor of the American origin. At first it was called the Neapolitan disease, the French pox, or *Morbus Gallicus*; and in 1530 Fracastorius, in a poem entitled “*Syphilis sive Morbus Gallicus*,” gave it the name by which it is now commonly known. The etymology of the name is uncertain.

At first the disease was thought to be transmitted like any other epidemic, but gradually the venereal nature was recognized, and Fernel, a famous Paris physician of the 16th century, insisted on the necessity of a primary inoculation. Paracelsus observed its congenital character. Throughout the 16th century the symptoms were well described. The disease appears to have been of much greater severity then than at present. Mercury and guaiacum were introduced as the important remedies. In the 18th century Lancisi recognized the relations existing between syphilis and aneurism, and Morgagni described many of the visceral lesions. Hunter, misled by inoculations made on his own person, decided in favor of the unity of the venereal poisons, gonorrhœa, soft chancre and syphilis. Ricord clearly differentiated the soft and hard chancre, and throughout the 19th century the clinical and pathological lesions were so thoroughly studied that scarcely a feature of the disease remained unknown. But all efforts at discovering the cause had failed, until in 1905 Schaudinn demonstrated the presence of a spirochæte in the lesions. Since then his work has been amply verified, and in 1910 Ehrlich announced the discovery of an arsenic compound with special spirochæticidal power.

Etiology: The Parasite.—The treponema is a spiral, curved organism from 5 to 15 μ in length, showing active movements in fresh specimens. It has been demonstrated in every tissue affected by the disease and has been found in semen. It lives only for a short time under natural conditions outside the body and is killed by weak antiseptics. It may live in the body as long as the host is alive. It is inoculable into monkeys, with the production of a disease resembling in most particulars that of man. The parasite has been cultivated by Noguchi.

There are possibly various strains of the treponema and this may explain

some of the clinical differences. Workers in the United States Army Medical School have grown spirochætes showing different results in the lesions produced by them. The spirochætes from cases of general paresis take 60 to 80 days for propagation and 60 days for lesions to be produced in rabbits, whereas in the case of organisms from early lesions three or four weeks is sufficient. A strain of spirochætes may result with greater resistance but perhaps less power of reproduction. The infection then does not cause any active symptoms, but may persist indefinitely in a latent form to resume activity after a long interval of quiescence. In some cases the tissues, so to speak, become accustomed to the spirochætes, antibodies are not produced, and in the absence of these the Wassermann reaction is negative. The infection must be active to cause the production of antibodies. In many cases a resistance of the parasite to the usual remedies is apparently established.

A most important result of the discovery of the parasite has been the application of serum diagnosis. The test known as the Wassermann reaction is a means of determining the presence of antibodies in the blood of a patient suffering from syphilitic infection. An enormous amount of work has been done upon it with the general result of confirming its value. A positive result has been obtained in from 90 to 95 per cent. of cases in the acute stages. It appears from the end of the second to the end of the fourth week, becomes more marked and may continue for an indefinite period. During active treatment it may be absent, to reappear again. Its intensity bears some relation to the activity of the lesions. In visceral and late congenital syphilis it is positive in a smaller percentage.

Modes of Infection.—(a) In a majority of all cases the disease is transmitted by *sexual congress*, but the designation *venereal disease* (*lues venerea*) is not always correct, as there are many other modes of inoculation. In the St. Louis Hospital collection there are illustrations of 26 varieties of extra-genital chancres.

(b) *Accidental Infection.*—In surgical and in midwifery practice physicians are not infrequently inoculated. Infection may occur without a characteristic local sore. Midwifery chancres are usually on the fingers, but may be on the back of the hand. The lip chancre is the most common of these extra-genital forms, and may be acquired in many ways apart from direct infection. Mouth and tonsillar sores result as a rule from improper practices. Wet-nurses are sometimes infected on the nipple, and it occasionally happens that relatives of a syphilitic child are accidentally contaminated.

(c) *Congenital Transmission.*—The disease is not inherited but the fetus is infected through the placenta. It is a question entirely of intra-uterine infection. The mother herself may be, and often is, apparently quite healthy, but the Wassermann reaction is present and it is through her and not directly from the father that the disease is transmitted. We can now understand what is known as Beaumès' or Colles' law, which was thus stated by the distinguished Dublin surgeon: "That a child, born of a mother who is without obvious venereal symptoms, and which, without being exposed to any infection subsequent to its birth, shows this disease when a few weeks old, this child will infect the most healthy nurse, whether she suckle it, or merely handle and dress it; and yet this child is never known to infect its own mother, even though she suckle it while it has venereal ulcers of the lips and tongue."

Morbid Anatomy.—The typical *primary lesion*, or chancre, shows: (a) A diffuse infiltration of the connective tissue with small, round cells. (b) Larger epithelioid cells. (c) Giant cells. (d) Changes in the small arteries and veins, chiefly thickening of the intima. The sclerosis is due in part to this acute obliterative endarteritis. The related lymph nodes undergo hyperplasia and become indurated.

The *secondary lesions* of syphilis are too varied for description here. They consist of condylomata, skin eruptions, affections of the eye, etc.

The *tertiary lesions* consist of circumscribed tumors known as gummata, various skin lesions, and a special type of arteritis.

The most characteristic change is in the blood vessels, showing marked round cell infiltration in the adventitia and vasa vasorum. The process later involves the other coats of the arteries with fibrous changes in the media and hyaline changes in the intima. The vascular change is the key to the understanding of many of the lesions of syphilis. In the late visceral lesions there are parenchymatous changes and the formation of fibrous tissue.

Gummata.—Syphilomata occur in the bones or periosteum—here they are called nodes—in the muscles, skin, brain, lungs, liver, kidneys, heart, testes, and adrenals. They vary in size from small, almost microscopic bodies to large solid tumors from 3 to 5 cm. in diameter. They are usually firm and hard, but in the skin and on the mucous membranes they tend to break down and ulcerate. On cross-section a medium-sized gumma presents in the centre caseous substance and at the periphery translucent, fibrous tissue.

Pathogenesis.—There are many gaps in our knowledge of what happens in syphilitic infection. The infection is by inoculation followed by immediate dissemination of the spirochaetes throughout the body. There is a general infection within a few days of inoculation, possibly within twenty-four hours. What is the result? The answer varies and it is tempting to ascribe the variations to possible differences in strains of spirochaetes and to the strength of the individual's resistance. The first evident response to the infection is the appearance of a reaction at the point of inoculation—the chancre—but this does not occur in every case or is not marked in every case. Is this due to the particular spirochaete or to the patient? The local lesion, when typical, represents an exudate of plasma cells and lymphocytes especially around the blood vessels, which show marked changes. (It may be said that histologically syphilitic lesions are essentially the same at all stages.) The surface of the chancre usually becomes eroded, but not always, with the production of an ulcer, the serum from which contains large numbers of spirochaetes. If untreated, the primary lesion lasts for a month or so and in healing marked induration occurs which may be permanent. Years later, spirochaetes may be found in the scar of the primary lesion.

The general infection results in evident changes after an interval of six to eight weeks. These show great variety, from severe general manifestations to signs so slight that they are not noted. The evidence of infection, fever, rash, etc., are much like those in the acute exanthemata but requiring a longer period for development. Hence the designation of syphilis as “a fever diluted by time.” Does an active response in this stage of acute general infection represent a stronger resistance? It may, and when we compare the percentage of patients in this stage who show evidence of involvement of the nervous sys-

tem with the much smaller percentage who show later involvement, there is basis for the suggestion that the body resistance may be able to overcome the spirochætes to some extent. Can the body overcome the infection entirely by its own resistance? We do not know.

This acute or secondary stage lasts for an uncertain time, usually months and rarely a year, and then in the majority of cases the manifestations of infection disappear forever in some patients, for varying periods in others. The surmise is that the spirochætes and body cells settle down to a relationship which may be amicable or the reverse. There does not seem any doubt that in some individuals the spirochætes live in certain tissues for the rest of the patient's life without causing any evident disease. The patient has the spirochætal infection but does not have clinical syphilis. In a smaller number the infection progresses so that there is really no interval between the acute secondary features and the usual late chronic involvement. In fact the two may be present together. In the majority, after the acute stage a period of quiescence results, usually for years, and subsequently more chronic manifestations appear, especially in the viscera. As to what determines their appearance we know very little; trauma may do it. In some cases there may not be any quiescent stage; the process advances very slowly and years are required before the damage is sufficient to be recognized clinically.

II. ACQUIRED SYPHILIS

Primary Stage.—This extends from the appearance of the initial sore until the onset of the constitutional symptoms, and has a variable duration of six to twelve weeks. The initial sore usually appears in a month after inoculation, and it first shows itself as a small red papule, which gradually enlarges and breaks in the centre, leaving a small ulcer. The tissue about this becomes indurated so that it ultimately has a gristly, cartilaginous consistence—hence the name, hard or indurated chancre. The size attained is variable, and when small the sore may be overlooked, particularly if it is just within the urethra. The initial lesion has no invariable characteristic and may not be indurated. It must be emphasized that infection may occur without any marked primary lesion which may be only a superficial erosion or ulceration. A negative history as to the occurrence of a chancre is of no value in excluding the possibility of infection. There are a considerable number of extragenital infections. Syphilitic infection may occur with a chancroid. The glands in the lymph-district of the chancre enlarge and become hard. Suppuration both in the initial lesion and in the glands may occur as a secondary change. The general condition of the patient in this stage is good. There may be no fever and no impairment of health. Even at this stage there is a general infection; in 49 of 221 cases with chancre changes in the spinal fluid were found (Wile and Hasley); in 8.83 per cent. of 283 cases (Mills, 1927).

Secondary Stage.—The constitutional symptoms usually appear within three months of the appearance of the primary sore. They rarely occur earlier than the sixth or later than the twelfth week:

(a) Fever, slight or intense, and very variable in character, may occur before the skin rash; more frequently it is the "fever of invasion" with the secondary symptoms, or it may occur at any period. It may be a mild con-

tinuous pyrexia or with marked remissions, but the most remarkable form is the intermittent, often mistaken for malaria. The fever may reach 105° and the paroxysms persist for months.

(b) *Anæmia*.—Some patients show a muddy pallor of the skin. A moderate grade of secondary anæmia is common and occasionally this becomes severe. The red cells do not show any special alterations. In some patients mercury causes a rapid anæmia, the hæmoglobin falling more rapidly than the red cells. There may be a moderate leucocytosis with an increase in the lymphocytes.

(c) *Cutaneous Lesions*.—The earliest and most common is a *macular syphilide* or *syphilitic roseola*, which occurs on the trunk and on the front of the arms. The face is often exempt. The spots, which are reddish-brown and symmetrically arranged, persist for a week or two. There may be multiple relapses of roseola, sometimes at long intervals, even eleven years (Fournier). The *papular syphilide*, which forms acne-like indurations about the face and trunk, is often arranged in groups. Other forms are the *pustular rash*, which may closely simulate variola, and a *squamous syphilide* not unlike ordinary psoriasis, except that the scales are less abundant. The rash is more copper-colored and not specially confined to the extensor surfaces. The rash tends to be polymorphous.

In the moist regions of the skin, such as the perineum and groins, and at the angles of the mouth, the so-called *mucous patches* occur, which are flat, warty outgrowths, with well-defined margins and surfaces covered with a grayish secretion. They are among the most distinctive lesions of syphilis.

The hair may fall out (*alopecia*), either in patches or by a general thinning. Occasionally the nails become affected (*syphilitic onychia*).

(d) *Mucous Lesions*.—With the fever and the roseolous rash the throat and mouth become sore. The pharyngeal mucosa is hyperæmic, the tonsils are swollen and often present small, kidney-shaped ulcers with grayish-white borders. Mucous patches are seen on the inner surfaces of the cheeks and on the tongue and lips. There may be a smooth glossitis with glistening areas over which the papillæ disappear. Hypertrophy of the papillæ in various portions of the mucous membrane produces the syphilitic warts or condylomata which are most frequent about the vulva and anus.

(e) *Adenitis*.—This is often general. The glands are hard, painless and not much enlarged. Involvement of the epitrochlear and posterior cervical glands is specially significant.

(f) *Arthritis* is not rare; it is often symmetrical, likely to be of long duration, if untreated, apt to relapse, may be quite acute but rarely causes serious damage. It may be so acute and severe that rheumatic fever is suspected. *T. pallidum* has been found in the synovial fluid.

The bones may be attacked and periostitis occur. Involvement of the spine, especially in the cervical region, may be found. Syphilitic spondylitis is not uncommon.

(g) *Nervous System*.—Even at the time of the primary lesion changes may be found in the spinal fluid. In the secondary stage the percentage showing meningeal involvement increases; some studies give 80 per cent. but probably 30 to 40 per cent. is more correct. Of symptoms *headache* is common, often occipital and passing up to the top of the head; it is usually worse

at night. There may be frequent acute general pains, possibly due to meningeal irritation.

(h) *Other Lesions.*—*Iritis* is common, and usually affects one eye before the other. It comes on from three to six months after the chancre. There may be only slight ciliary congestion in mild cases, but in severer forms there is great pain, and the condition is serious. *Choroiditis* and *retinitis* are rare secondary manifestations. *Pupillary changes* are not uncommon in the early stages. *Ear affections* are not common in this stage, but sudden deafness occurs, which may be due to labyrinthine disease or to the extension of inflammation from the throat to the middle ear. The *spleen* may be enlarged. *Epididymitis* and *parotitis* are rare. *Jaundice* may occur, even in the primary stage, the *icterus syphiliticus præcox*. The acute nephritis will be referred to later. Disease of the cardiovascular system is not common.

Tertiary Stage.—No hard and fast line can be drawn between the lesions of the secondary and those of the tertiary period; and, indeed, in exceptional cases, manifestations which usually appear late may appear before the primary sore has properly healed. The special affections of this stage are certain skin eruptions, visceral lesions, and amyloid degeneration. In all the late lesions the importance of the involvement of the arteries must be remembered.

(a) The late *syphilides* show a great tendency to ulceration and destruction of the deeper layers of the skin, so that in healing scars are left. They are also more scattered and seldom symmetrical. One of the most characteristic of the syphilides is *rupia*, the dry stratified crusts of which cover an ulcer which involves the deeper layers of the skin and in healing leaves a scar.

(b) *Gummata.*—These may occur in the skin, tissues of the mouth, subcutaneous tissue, muscles, or internal organs. In the skin they tend to break down and ulcerate, leaving ugly sores which heal with difficulty. In the solid organs they undergo fibroid transformation and produce puckering and deformity. On the mucous membranes these lesions lead to ulceration, in the healing of which cicatrices are formed; thus, in the larynx great narrowing may result, and in the rectum ulceration with fibroid thickening and retraction may lead to stricture. Gummatous ulcers may be infective.

(c) *Amyloid Degeneration.*—Syphilis plays a most important rôle in the production of this affection. Of 244 instances analyzed by Fagge, 76 had syphilis, and of these 42 had no bone lesions. It follows the acquired form and is very common in association with rectal syphilis in women. In congenital lues amyloid degeneration is rare.

(d) *Syphilis of the Bones.*—This is not uncommon and should be searched for by radiography in doubtful cases. The commonest lesions are *periostitis* and *osteo-periostitis* which may exist without any symptoms. Occasionally a *gumma* is found. *Bursitis* occurs rarely and is usually very chronic. The bone lesions occur both in the acquired and congenital form. *Pain* is common, often nocturnal and relieved by exercise. It may occur only on pressure over small areas. Involvement of the *spine* is not unusual. There may be *periostitis*, *osteomyelitis* with necrosis, and sometimes the formation of *exostoses*, which may be felt. The cervical region is most often involved and the process is generally limited to a small number of vertebræ.

The main features are pain, tenderness, rigidity, and sometimes deformity. In a number of patients neural symptoms are present and root pains may be marked. The degree of deformity varies. There is often marked muscle spasm in the region involved and hypotonicity in other parts of the spine. Involvement of the cord itself is comparatively common. The *diagnosis* of involvement of the spine may not be easy. Careful search should be made for luetic lesions elsewhere; for example, ulceration of the larynx has been found in some cases of involvement of the cervical region.

Syphilitic myositis affects the calf and sterno-mastoid muscles especially.

Quaternary Stage.—Long years it may be from the primary sore and from any active manifestations, certain forms of syphilis may appear, the chief of which are *tabes dorsalis* and general paresis.

Latent Syphilis.—In many cases there is a persistence of the spirochætal infection without evident clinical signs of the disease, proved (post mortem) by the presence of the spirochætes in certain tissues, especially the heart, aorta and testicles. The essential lesion is a chronic inflammatory process with an accumulation of lymphocytes and plasma cells about the lymphatics and blood vessels leading to fibrosis and atrophy of the parenchyma. Warthin has drawn especial attention to this and has demonstrated the organisms in about one-third of autopsies on adults. Careful examination will often show clinical evidence in the form of myocarditis, aortitis, or induration of the testicle. Warthin suggests that latent syphilis is the chief factor in causing myocardial insufficiency and the cardiovascular-renal complex. The Wassermann reaction and examination of the spinal fluid are useful in the recognition of these cases.

III. CONGENITAL SYPHILIS

With the exception of the primary sore, every feature of the acquired disease may be seen in the congenital form. The intra-uterine conditions leading to the death of the fetus do not here concern us. The child may be born healthy-looking or with well-marked evidences of the disease. In the majority of instances the former is the case and within the first month or two the signs of the disease appear.

Symptoms.—(a) *At Birth.*—When the disease exists at birth the child is feebly developed and wasted, and a skin eruption is usually present, commonly in the form of bullæ about the hands and feet (*pemphigus neonatorum syphiliticus*). The child snuffles, the lips are ulcerated, the angles of the mouth fissured, and there is enlargement of the liver and spleen. The bone changes may be marked, and the epiphyses may be separated. Osteochondritis is common. In such cases the children rarely survive long.

(b) *Early Manifestations.*—When born healthy the child thrives, is fat and plump, and shows no abnormality; then from the fourth to the eighth week, rarely later, a nasal catarrh occurs, syphilitic rhinitis, which impedes respiration, and produces the characteristic snuffles. The discharge may be sero-purulent or bloody. The child nurses with great difficulty. In severe cases ulceration takes place with necrosis of the bone, leading to a depression at the root of the nose and a characteristic deformity. This coryza may be

mistaken for an ordinary catarrh, but the coexistence of other manifestations usually makes the diagnosis clear. The disease may extend into the Eustachian tubes and middle ears and lead to deafness.

The *cutaneous* lesions arise with or shortly after the onset of the snuffles. The skin often has a sallow, earthy hue. The eruption is first noticed about the nates. There may be an erythema or an eczematous condition, but more commonly there are irregular reddish-brown patches with well-defined edges and a papular syphilide is not uncommon. A desquamative dermatitis of the palms of the hands and soles of the feet may occur. Fissures occur about the lips, either at the angles of the mouth or in the median line. These *rhagades*, as they are called, are very characteristic. There may be marked ulceration of the muco-cutaneous surfaces. The secretions from these mouth lesions are very virulent, and it is from this source that the wet-nurse is usually infected. Not only the nurse, but members of the family, may be infected; other children have been accidentally inoculated from a syphilitic infant. The hair of the head or of the eyebrows may fall out. The syphilitic *onychia* is not uncommon. Enlargement of the glands is not so frequent in the congenital as in the acquired disease. When the cutaneous lesions are marked the contiguous glands can usually be felt. As pointed out by Gee, the *spleen* is enlarged in many cases. Enlargement of the *liver*, though often present, is less significant, since in infants it may be due to various causes. The child may be restless and wakeful, particularly at night. Some writers describe a peculiar hoarse syphilitic cry. Among rare manifestations are hæmorrhages—the *syphilis hæmorrhagica neonatorum*. The bleeding may be subcutaneous, from the mucous surfaces, or, when early, from the umbilicus. All of such cases, however, are not syphilitic, and the disease must not be confounded with the acute hæmoglobinuria of new-born infants. E. Fournier described a remarkable enlargement of the subcutaneous veins. Acute infections may stir up latent congenital syphilis.

(c) *Late Manifestations*.—Children with congenital syphilis rarely thrive. Usually they present a wizened, wasted appearance, and a prematurely aged face. In the patients who recover the general nutrition may remain good and the child may show no further manifestations; commonly, however, at the period of *second dentition* or at *puberty* the disease reappears. Although the child may have recovered from the early lesions, it does not develop like other children. Growth is slow, development tardy, both mental and physical, and there are facial and cranial characteristics which often render the disease recognizable at a glance. A young man of nineteen or twenty may neither look older nor be more developed than a boy of ten or twelve—infantilism. The forehead is prominent, the frontal eminences are marked, and the skull may be very asymmetrical. The bridge of the nose is depressed, the tip *retroussé*. The lips are often prominent, and there are striated lines running from the corners of the mouth. The teeth are deformed and may present appearances which Jonathan Hutchinson claimed are specific and peculiar. The upper central incisors of the permanent set are peg-shaped, stunted in length and breadth, and narrower at the cutting edge than at the root. On the anterior surface the enamel is well formed, and not eroded or honeycombed. At the cutting edge there is a single notch, usually shallow, sometimes deep, in which the dentine is exposed. The upper first large molar may have a

supernumerary cusp on the inner side which forms a protuberance but this is not peculiar to syphilis. (*mulberry*)

Among late manifestations, particularly apt to appear about puberty, is the interstitial keratitis, which usually begins as a slight steaminess of the cornea, which present a ground-glass appearance. It affects both eyes, though one is attacked before the other. It may persist for months and leave opacities, which prevent clear vision. Strabismus is relatively common. Iritis and choroiditis may occur. Of ear affections, apart from those which follow the pharyngeal disease, a form occurs, about the time of puberty or earlier, in which deafness comes on rapidly and persists in spite of treatment. It is unassociated with obvious lesions, and is probably labyrinthine in character. Bone lesions are not rare. Epiphysitis may occur with swelling and occasionally separation follows. It may simulate paralysis. Chronic periostitis, affecting especially the tibiae, usually appears after the sixth year and may cause marked deformity with great thickening of the bone (*sabre-tibia*). Nodes of congenital syphilis may be diffuse and affect the bones of arms and legs. They are generally symmetrical, rarely painful, may occur late, even after the twentieth year, and are often mistaken for rickets. Dactylitis, usually in the second or third year, causes fusiform swelling of the fingers, rarely of the toes. Arthritis may occur at any age; it is often symmetrical with swelling but comparatively slight disability or pain, and tends to be chronic.

Visceral lesions occur much as in the acquired form except that involvement of the central nervous system may result in lack of mental development. General paresis may result. Symptoms much like those of acute infectious chorea appear in some children. Enlargement of the spleen, sometimes of the lymph-nodes, may be a late manifestation, with or without disease of the liver. Much interest attaches to the influence of congenital syphilis on the endocrine glands. They may be disturbed leading to disorders of development and function. It is a good rule to consider congenital syphilis in any obscure abnormality in a child.

Is syphilis transmitted to the third generation? The discovery of the treponema answers this question. The disease can be carried through as many generations as are able to reproduce. This makes a thorough study of the family for several generations an important aid in the diagnosis of congenital syphilis.

IV. VISCERAL SYPHILIS

1. Cerebro-spinal Syphilis

The nervous system is frequently involved in the early stages as shown by changes in the cerebro-spinal fluid. In the great majority there are no later manifestations. Mattauschek and Pilcz followed 4,143 cases of syphilis for from twenty to thirty years with special reference to this point: 4.7 per cent. developed paresis, 3.2 per cent. had cerebro-spinal syphilis and 2.7 per cent. tabes dorsalis. The figures were highest in those who had little or no treatment.

Pathology.—The process may involve (a) the meninges, (b) the arteries and (c) the parenchyma. In the majority of cases the lesions are not limited

to one of these structures. Predominant involvement of one alone is probably most common in the arteries—endarteritis. With this the cerebro-spinal fluid shows little if any change and the symptoms are due to the vascular disease. It is a mistake to carry any classification too far because vascular and meningeal lesions of some grade occur in practically all cases. In all forms marked perivascular changes are common. The exudate due to these interferes with the lymphatic circulation. This with the endarteritis often results in marked interference with the blood supply. In general the lesions may be classified as (1) parenchymatous, which includes tabes and paresis, and (2) interstitial, which comprises the forms usually termed cerebro-spinal syphilis.

The parenchymatous lesions appear as a rule later than the interstitial, but there is often a history of earlier nervous symptoms which responded quickly to treatment. These are usually due to a basilar meningitis. The interval suggests that there has been a slow process gradually advancing which gives time for degenerative processes to develop. The majority of the cases of the interstitial type appear within five years of infection.

(a) *Meninges*.—Meningitis is common and occurs particularly at the base, about the chiasm and along the Sylvian fissures. *Gummata* form, attached to the pia mater, sometimes to the dura; they are most common in the cerebrum. They form definite tumors varying in size from a pea to a walnut and are usually multiple. They are rarely found unassociated with the meninges. When small they have a uniform, translucent appearance, but when large the centre undergoes a fibrocaseous change with a firm grayish tissue at the periphery. They may resemble tuberculous tumors and occasionally undergo cystic degeneration. Large growths are not so common in the cord. Intense encephalitis or myelitis may occur in the neighborhood of a gumma. There are cases of acute syphilitic meningitis, some with a negative Wassermann reaction, which are rapidly fatal.

In the brain, gummatus arteritis is a common cause of softening, which may be extensive, as when the middle cerebral artery is involved, or when there is a large patch of meningitis. In such cases the process is really a meningo-encephalitis and the symptoms are due to the secondary changes.

(b) *Arteries*.—A common lesion is the typical progressive endarteritis. Perivascular changes are common. There may be a marked inflammatory reaction with cedema and resulting interference with the lymphatics or small nodular tumors on the vessels which may break down or lead to rupture. Arterial disease is often combined with lesions in the meninges.

(c) *Parenchyma*.—The changes here are largely degenerative and are due partly to interference with nutrition by the vascular lesions and partly to the direct action of toxins from spirochaetes in the tissues (especially in paresis). It is evident that lesions of the meninges and vessels offer much more hope of benefit from treatment than those of the parenchyma.

Cerebro-spinal Fluid.—The examination of this is of great value in diagnosis and in estimating the effect of treatment. The special points in cerebro-spinal syphilis are: (a) *Cell Content*.—A lymphocytosis occurs in 85-90 per cent. of cases. The cells are often over 100 and may reach 1,000 per c.mm., the number being some guide to the intensity of the meningitis. With endarteritis alone the cells may be normal.

(b) *Globulin*.—An increase is present in 90-95 per cent. of cases. It prob-

ably represents abnormal transudation from damaged vessels and may occur in a great variety of conditions. An increase in globulin may be the only change in the fluid in the early secondary period.

(c) *Wassermann Reaction*.—This is positive in 85-90 per cent., and indicates some active process in the cerebro-spinal tissues. In the early secondary period it may be absent even with increase in cells and globulin.

(d) *Colloidal Gold Reaction*.—This is present in 75-80 per cent. of cases. The type of curve is useful in distinguishing paresis from tabes and cerebro-spinal syphilis.

Symptoms.—The onset is usually within one to five years after infection but it may be earlier. Headache, often worse at night, irritability and mental fatigue may be prodromal symptoms. The clinical features are many, occur in various combinations and naturally vary depending on the relative degree of involvement of meninges and vessels. The multiplicity of signs is often a great aid in diagnosis. Headache is usually marked. *Ocular* features are common and often show remarkable variations from time to time. The pupils may be unequal or irregular and react sluggishly to light. Ptosis, weakness of the eye muscles, diplopia and optic neuritis may be present. As a rule there is involvement of more than one of the cranial nerves.

(a) *Psychical Features*.—A sudden and violent delirium may be the first symptom or prior to the delirium there may have been headache, alteration of character, and loss of memory. The condition may be accompanied by convulsions. There may be no neuritis, no palsy, and no localizing symptoms.

(b) More commonly following headache, giddiness, or an excited state which may amount to delirium, the patient has an epileptic seizure or a hemiplegic attack, or there is involvement of the nerves of the base. Some of these cases display a prolonged torpor, a special feature of brain syphilis to which both Buzzard and Huebner have referred, which may persist for a month.

(c) In some cases the clinical picture is that of general paresis.

(d) Many cases of cerebral syphilis display the features of brain tumor—headache, optic neuritis, vomiting, and convulsions. Of these symptoms convulsions are the most important, and both Fournier and Wood laid great stress on the value of this symptom in persons over thirty. The first symptoms may, however, be those of embolism or thrombosis; thus there may be sudden hemiplegia, with or without loss of consciousness. The hemiplegia usually develops slowly and there may be weakness rather than paralysis.

The symptoms of *spinal syphilis* are extremely varied and may be caused by large gummatous growths attached to the meninges, in which case the features are those of tumor, by gummatous arteritis with secondary softening, by meningitis with secondary cord changes, or by late sclerosis. Syphilitic myelitis will be considered under affections of the spinal cord.

Diagnosis.—The history is of the first importance, but it may be extremely difficult to get a trustworthy account. Careful examination should be made for traces of a primary sore, for scars on the skin, and for bone lesions. The oculo-cardiac reflex may be absent. The character of the symptoms is often of great assistance. They are multiform, variable, and often such as could not be explained by a single lesion; thus there may be anomalous spinal symptoms or involvement of the cranial nerves on both sides. The study of the spinal fluid and the Wassermann reaction in it and in the blood are of the

greatest aid. The result of treatment has a bearing as the symptoms may disappear with the use of anti-syphilitic remedies.

Prognosis.—This is always uncertain and depends largely on the extent of arterial disease. With marked arteritis and secondary softening the possibilities of restoration are slight. Meningeal disease is much more hopeful. Much depends on early recognition and prompt treatment. The tendency to relapse is marked. In the case of large gummata the problem is practically that of brain tumor.

2. *Syphilis of the Respiratory Organs*

Syphilis of the Trachea and Bronchi.—L. A. Conner has analyzed 128 recorded cases of syphilis of the trachea and bronchi. In 52 per cent. of the cases the trachea was alone involved. In only 10 per cent. were characteristic lesions of syphilis found in the lungs. Bronchial dilatation below the lesion was found in 15 per cent. of the cases. In 10 cases the lesion occurred in congenital syphilis. The *symptoms* are often of obstruction, *dyspnoea*, often paroxysmal, stridor, prolonged inspiration and a hard paroxysmal cough.

Syphilis of the Lung.—This is a rare disease. In 2,800 post mortems at the Johns Hopkins Hospital there were 12 cases with syphilitic disease in the lungs; in 8 of these the lesions were in congenital syphilis. In 11 cases there were definite gummata. Clinically the presence of syphilis of the lung was suspected in three cases. Fowler, in the museums of the London hospitals and the Royal College of Surgeons, found only 12 specimens of syphilitic lesions of the lungs, two of which are doubtful. For a consideration of pulmonary syphilis, the reader is referred to Fowler and Godlee's work on Diseases of the Lungs.

It occurs under the following forms:

(a) *The White Pneumonia of the Fetus.*—This may affect large areas or an entire lung, which then is firm, heavy, and airless, even though the child may have been alive. On section it is grayish-white—the so-called white hepatization of Virchow. The chief change is in the alveolar walls, which are greatly thickened and infiltrated, and the section is like one of the pancreas. In the early stages, for example in a seven or eight months' fetus, there may be scattered miliary foci of this induration chiefly about the arteries. The air-cells are filled with desquamated and swollen epithelium.

(b) In the form of *gummata*, which vary in size from a pea to an egg. They occur irregularly through the lung, but, as a rule, are more numerous toward the root. They present a grayish-yellow caseous appearance, are dry and usually imbedded in a translucent, more or less firm, connective tissue. In a case described by Councilman there was extensive involvement of the root of the lungs. Bands of connective tissue passed inward from the thickened pleura, and between these strands and surrounding the gummata there was in places a mottled red pneumonic consolidation. In rare instances there are extensive caseous gummata with softening and formation of *bronchiectatic* cavities, and clinically a picture of pulmonary tuberculosis without the presence of tubercle bacilli. Bronchiectasis in children may be due to syphilis.

(c) *A Form Suggesting Tuberculosis.*—Areas may be involved either at the root, or at the apex or base of the lung. The physical signs are much as in

tuberculosis. There may be cough, possibly with a good deal of sputum, sometimes blood-streaked, loss of weight and fever, with signs at one apex or base. The picture may suggest tuberculosis but tubercle bacilli are not found. The condition may persist for a considerable time without very marked change. The *diagnosis* is difficult. C. P. Howard gives the following points as important: (1) Symptoms out of proportion to the physical signs; (2) absence of tubercle bacilli; (3) history; (4) a positive Wassermann reaction; (5) evidence of syphilis elsewhere; and (6) the therapeutic test. The signs may suggest advanced tuberculosis. In one case, a man aged twenty-seven had cough and bloody expectoration for a year and died of severe hæmoptysis. Bacilli were never found in the sputum. There were extensive caseous gummata throughout both lungs, with much fibrous thickening, and in a lower lobe a cavity 3 by 5 cm. in diameter, on the wall of which a branch of the pulmonary artery was eroded.

(d) A majority of authors follow Virchow in recognizing the fibrous interstitial pneumonia at the root of the lung and passing along the bronchi and vessels as probably syphilitic. This much may be said, that in certain cases gummata are associated with these fibroid changes. Again, this condition alone is found in persons with well-marked syphilitic history or with other visceral lesions. It seems in many instances to be a purely sclerotic process, advancing sometimes from the pleura, more commonly from the root of the lung, and invading the interlobular tissue, gradually producing a more or less extensive fibroid change. It rarely involves more than a portion of a lobe or portions of the lobes at the root of the lung. The bronchi are often dilated.

Diagnosis.—It is to be borne in mind that hospital physicians and pathologists the world over bear witness to the extreme rarity of lung syphilis. In the second place, the therapeutic test upon which so much reliance is placed is by no means conclusive. With pulmonary tuberculosis there should be no confusion, owing to the readiness with which the presence of bacilli is determined. Bronchiectasis in a lower lobe, dependent upon an interstitial fibrosis of syphilitic origin, could not be distinguished from any other form of the disease. Tuberculosis in a syphilitic subject has no special peculiarities and the lesions of syphilis and tuberculosis can coexist in a lung.

Prognosis.—Evidently this depends on the character of the lesions as fibrosis cannot be greatly influenced. In general the patients can be markedly helped if not made well.

3. *Syphilis of the Liver*

Varieties.—(a) *Congenital.*—Gubler in 1852 described the diffuse hepatitis which occurs in a large percentage of all deaths in congenital lues. While there may be little or no macroscopic change, the liver preserves its form and is usually enlarged, hard and resistant, and has a yellowish color, compared by Trousseau to sole-leather. Small grayish nodules may be seen on the section. In other cases there are definite gummata with extensive sclerosis. The spirochætes are present in extraordinary numbers.

The child may be still-born, die shortly after birth, or may be healthy when born and the liver enlarges within a few weeks. The organ is firm; the edge may be readily felt, usually far below the navel. The spleen is also

enlarged. The features are those of cirrhosis, but jaundice and ascites are not common. Hochsinger states that of 45 cases recovery took place in 30.

(b) *Delayed Congenital Syphilis.*—The condition is by no means rare. Of 132 cases of syphilis hereditaria tarda collected by Forbes, in 34 the liver was involved. The children are nearly always ill-developed, sometimes with marked clubbing of the fingers and showing signs of infantilism. Jaundice is rare. The liver is usually enlarged, or it may show nodular masses.

ACQUIRED SYPHILIS.—(a) In the *secondary* and sometimes in the *primary stage* the liver may be slightly enlarged. Jaundice may occur coincident with the rash and the adenitis. Rolleston thinks it is probably due to a catarrhal condition of the smaller ducts, part of a general syphilitic hepatitis. There are cases in which it has passed on to a state of acute yellow atrophy. The prognosis is generally good.

(b) *Tertiary Lesions.*—The frequency with which the liver is involved in syphilis in adults is very variously estimated. J. L. Allen, quoted by Rolleston, found 37 cases of hepatic gummata among 11,629 autopsies at St. George's Hospital; in 27 cases cicatrices alone were present. Flexner at the Philadelphia Hospital found 88 cases of hepatic syphilis among 5,088 autopsies. Among 2,300 autopsies at the Johns Hopkins Hospital there were 47 cases of syphilis of the liver, gummata in 19, scars in 16, cirrhosis in 21 cases; 6 of the cases were congenital. Some authorities hold that syphilis is an important factor in the etiology of portal cirrhosis.

Anatomically the lesions may be gummata, scars or a syphilitic sclerosis. The gummata range in size from a pea to an orange. When small they are pale and gray; the larger ones present yellowish centres; but later there is a "pale, yellowish, cheese-like nodule of irregular outline, surrounded by a fibrous zone, the outer edge of which loses itself in the lobular tissue, the lobules dwindling gradually in its grasp. This fibrous zone is never very broad; the cheesy centre varies in consistence from a gristle-like toughness to a pulpy softness; it is sometimes mortar-like, from cretaceous change" (Wilks). They may form enormous tumors, as in the remarkable one figured in Rolleston's work on Diseases of the Liver. They may be felt as large as an orange beneath the skin in the epigastrium and may disappear with the same extraordinary rapidity as the subcutaneous gumma. Macroscopically they may look like a massive cancer. Extensive caseation, softening and calcification may occur. The syphilitic scars are usually linear or star-shaped. They may be very numerous and divide the liver into small sections—the so-called botryoid organ, of which a remarkable example is figured in the Lectures on Abdominal Tumors (Osler).

Symptoms.—In the first place, the clinical picture may be that of cirrhosis—slight jaundice, fever, portal obstruction, ascites. The liver is enlarged and may be smooth. There may not be the slightest suspicion of the syphilitic nature of the case. One of our patients had been tapped thirteen times before admission to the hospital. The diagnosis was made by finding gummata on the shins. She recovered promptly.

In a second group the liver is enlarged, sometimes with a marked round prominence. The surface may be smooth throughout or with nodular enlargement in places. In some of these cases amyloid change may have occurred.

Thirdly, in a very important group the symptoms are those of tumor of the liver, causing pain and distress, and on examination an irregular or nodular mass is discovered. A friction rub may be heard over it. Naturally carcinoma is thought of, as there may be nothing to suggest syphilis. Lastly, irregular fever with enlargement and irregularity of the liver may suggest suppuration or gall-bladder disease, or the uniform great enlargement of the organ hypertrophic biliary cirrhosis, while in some cases the spleen is so greatly enlarged and the anæmia so pronounced, and the liver so contracted that the diagnosis of splenic anæmia is made.

Diagnosis.—Syphilis of the liver is much commoner clinically than the autopsy figures suggest. It should be considered in every case of hepatic disease in which the diagnosis is obscure and in some in which it seems clear. The liver may show a great variety of changes. Relatively greater enlargement of the left lobe is always suggestive of syphilis. The spleen is often enlarged. Signs of syphilis elsewhere are important and the therapeutic test is of value because the response is usually so marked. This applies particularly to the fever which usually disappears within two or three days after iodide is begun. The Wassermann reaction is negative in a proportion of the cases and no weight should be given to its absence. It may be given by the ascitic fluid when the blood is negative.

Prognosis.—This is better than in other forms of visceral syphilis if recognized before marked damage is done. The recurrence of symptoms after thorough treatment is rare. Arsenic compounds should not be given on account of the danger of severe damage to the liver cells.

4. Syphilis of the Digestive Tract

The base of the tongue may show obliteration of the usual surface markings with smoothness of the surface and induration of the tissues due to fibroid change. The salivary glands are rarely involved, the parotid most often. The œsophagus may show œsophagitis in the acute stage. Later a gumma may be present followed by ulceration, infiltration, fibrosis and stenosis. There is pain with difficulty in swallowing and, if there is obstruction, malignant disease may be diagnosed. Examination with the œsophagoscope and the serological tests are important. The frequency of syphilis of the stomach is difficult to estimate. There is no definite clinical picture, the symptoms depending on the site and extent of the lesion. There may be the usual features of dyspepsia or ulcer, or the findings may suggest carcinoma. A positive serological test and rapid improvement under specific treatment are suggestive, but gastric disease and ulcer in patients with syphilis are not necessarily due to it. Syphilitic ulceration has been found in the small intestine and in the cæcum. The frequency of syphilis of the pancreas is uncertain. Warthin regards interstitial pancreatitis as common in latent syphilis. The spleen is often enlarged with or without liver involvement.

Syphilis of the rectum is most common in women, and results from the growth of gummata in the submucosa above the internal sphincter. The symptoms are usually those of narrowing of the lower bowel. The condition is readily recognized by rectal examination. The history of gradual on-

coming stricture, the state of the patient, and the fact that there is a hard, fibrous narrowing, not an elevated crater-like ulcer, usually render easy the diagnosis from malignant disease. In medical practice these cases may come under observation for other symptoms, particularly amyloid degeneration; the rectal disease may be overlooked, and only discovered post mortem.

5. *Circulatory System*

Syphilis of the Heart.—A fresh, warty *endocarditis* due to syphilis is not recognized, though occasionally in persons dead of the disease this form is present, as is not uncommon in conditions of debility.

The frequency of the association of syphilis with myocardial changes, anæmic necrosis, and coronary artery disease has long been known. It is only since the introduction of newer methods that we have been able to determine how frequently the heart and aorta are the seat of syphilitic infection. Warthin made a study of 200 hearts, 50 from congenital and 150 from acquired syphilis, from which he groups the primary lesions of cardiac syphilis as follows: Large colonies of spirochætes may be found in the myocardium in congenital and in the active stages of acquired syphilis without definite changes in the heart muscle. An œdema with loss of striation is not uncommon. A focal degeneration may be the only lesion, or there may be areas of necrosis 5 mm. in diameter; a striking feature is the presence of myxoma-like translucent areas which contain spirochætes in large numbers. Interstitial changes are common, œdema associated with the presence of numerous spirochætes and leukocytes. Interstitial proliferation, usually perivascular, may be the earliest recognizable lesion. A transition is found between focal œdema and small, sharply localized non-caseating gummata. It is interesting to note that spirochætes may be found in great numbers in the myocardium when not found elsewhere in the body.

Involvement of the *myocardium* may occur in the secondary stage but is usually more marked later. There may be degeneration, sometimes secondary to coronary artery disease or fibroid changes. With the development of fibrosis the capillaries are obliterated and the muscle fibres atrophy. Epicardial changes, with peri-arteritis, are common. The *symptoms* are those of slight cardiac insufficiency with a varying amount of precordial pain, sometimes vague, sometimes severe and localized. There may be increase in rate and some irregularity with a soft apex systolic murmur, not transmitted, and increased by exercise. Later the signs are those of myocarditis with pain and precordial tenderness; the pain may suggest angina pectoris. The association of pain with signs of myocarditis in a young adult should suggest the possibility of syphilis. The pain differs in position from that of acute aortitis which may be associated with it. Dyspnœa is often marked. The giving of mercury often results in rapid improvement. Rupture or sudden death may take place; indeed, sudden death is frequent, occurring in 21 of 63 cases (Mracek).

Syphilis of the Arteries.—Syphilis plays an important rôle in arteriosclerosis, aortitis and aneurism. Its connection with these processes will be considered later; here we shall refer only to the syphilitic affection of the smaller vessels, which occurs in two forms:

(a) An obliterating endarteritis, characterized by a proliferation of the subendothelial tissue. The new growth lies within the elastic lamina, and may gradually fill the entire lumen; hence the term obliterating. The media and adventitia are also infiltrated with small cells. This form of endarteritis is not characteristic of syphilis, and its presence alone in an artery could not be considered pathognomonic. If, however, there are gummata in other parts, or if the condition about to be described exists in adjacent arteries, the process may be regarded as syphilitic.

(b) Gummatous Periarteritis.—With or without involvement of the intima, nodular gummata may develop in the adventitia of the artery, producing globular or ovoid swellings, which may attain considerable size. They are not infrequent in the cerebral arteries, which seem to be specially prone to this affection. This form is specific and distinctive of syphilis. Many observers have found *Treponema pallidum* in the syphilitic aortitis, and also in gummatous arteritis of the cerebral vessels.

6. Syphilis of the Urinary Tract

Kidney.—Acute nephritis is estimated to occur in the secondary stage in 3 to 4 per cent., and may occur in from three to six months, sometimes later, from the initial lesion. The outlook is good, though often the albuminuria may persist for months; more rarely chronic nephritis follows. In a few instances syphilitic nephritis has proved rapidly fatal in a few weeks. Both in congenital and acquired syphilis Warthin has shown a marked localization of the spirochaetes in the kidneys with evidence of excretion through the epithelium, chiefly in the convoluted tubules. The spirochaetes have been found in the urine in a few cases. Gummata occasionally are found in the kidneys, particularly in cases with extensive gummatous hepatitis. They are rarely numerous, and occasionally lead to scattered cicatrices. Clinically the affection is not recognizable.

Bladder.—This is not common, but should be considered in cases of unexplained frequency of painful urination with hæmaturia. Papilloma may be simulated and a gumma may suggest carcinoma. Involvement of the prostate is very rare; Thompson accepted 12 cases as proved. Warthin found the spirochaetes in one case in the prostate.

7. Syphilis of the Reproductive Organs

Testicle and Epididymis.—The testicle is a favorite site for the spirochaetes to settle. Orchitis occurs in congenital syphilis but is specially frequent in the acquired form. It occurs in two forms, interstitial and nodular (gumma), which may exist together. In the interstitial form the testicle (usually one only) is enlarged, smooth, not tender, the testicular sensation often being absent, heavy and with a distinct feeling of induration. Atrophy may follow. In the nodular form the testicle is irregular and if necrosis occurs the walls of the scrotum are involved with ulceration. The diagnosis has to be made from tuberculosis and neoplasm. The epididymis is involved rarely, with or without orchitis. A subacute process of short duration occurs

in the secondary stage and later there may be induration or a gumma. Syphilis of the *cord* is very rare.

Syphilis of the *ovary* in the form of a gumma has been reported. Gummata and marked vascular changes occur in the uterus but are rare.

Mammary Gland.—Syphilitic mastitis is found most often in women, is usually unilateral and occurs in acquired and congenital cases. There is a chronic diffuse hard infiltration or local nodules. The skin is rarely involved. The axillary glands may be enlarged. The condition is very like carcinoma; the Wassermann reaction and therapeutic test are important.

V. DIAGNOSIS, TREATMENT, ETC.

Diagnosis.—GENERAL DIAGNOSIS.—There is seldom any doubt concerning the recognition of syphilitic lesions; but the number of persons, without any evident sign of the disease, in whom a positive serological reaction is found proves that a negative diagnosis cannot be based on the absence of history and clinical manifestations. Syphilis is common in the community, and is no respecter of age, sex, or station in life. The primary sore may have been of trifling extent, or urethral and masked by a gonorrhœa, and the patient may not have had severe secondary symptoms, or the infection may occur without any chancre and the secondary lesions may be so slight that they are not noticed. Inquiries should be made into the history to ascertain if the patient has had skin rashes, sore throat, or if the hair has fallen out. Careful inspection should be made of the throat and skin for signs of old lesions. Skin lesions with induration or scarring and a crescentic shape should excite suspicion. Scars in the groins, the result of buboes, are uncertain evidence of syphilitic infection. The cicatrices on the legs are often copper-colored, though this cannot be regarded as peculiar to syphilis. The bones should be examined for nodes. The scar of the primary sore may be found or there may be atrophy or induration of the testes. In women the occurrence of miscarriages and the bearing of stillborn children are always suggestive. In doubtful cases the study of the spinal fluid is important.

In the congenital disease, the occurrence within the first three months of snuffles and skin rash is conclusive. Later, the characters of the syphilitic facies often give a clue to the nature of some obscure visceral lesion. Other distinctive features are the symmetrical development of nodes on the bones and the interstitial keratitis.

The *Treponema pallidum* may be found in the fresh lesion. After cleaning carefully, serum is sucked out and the living spirochætes may be seen in the special "dark field" apparatus.

SERUM DIAGNOSIS.—The complement fixation test in good hands is a most valuable aid. It is obtained in the great majority of cases of syphilis with manifestations. The results in tabes and general paresis are very constant. But too much dependence should not be placed on the Wassermann or Kahn test, especially if negative. It is only one piece of evidence even if a valuable one. In congenital syphilis and in visceral disease it may be negative. Great caution should be used in the interpretation of "weakly positive" serological tests. Much harm has resulted from a conclusion that such mean a positive diagnosis of syphilis.

CUTANEOUS REACTION.—An emulsion or extract of pure cultures of *Treponema pallidum*—termed luetin—was introduced by Noguchi to obtain a skin reaction. The skin is sterilized and 0.05 c. c. injected intradermically. The local reaction is usually papular, and surrounded by a zone of redness, it may become pustular. There is very slight constitutional effect. The reaction is most constant and marked in tertiary and congenital cases; it is infrequent, and mild in the primary and secondary stages, in the latter of which the complement fixation test is more constant. The cutaneous reaction may be given by non-syphilitics who have been taking iodide.

THERAPEUTIC TEST.—In a doubtful case, as, for example, an obstinate skin rash or an obscure tumor in the abdomen, antisyphilitic treatment may prove successful, but this cannot always be relied upon.

Prognosis.—As regards life, a fatal result is rare in the early stages in the acquired but frequent in the congenital form. When manifestations are present at birth or appear shortly after it the outlook is always serious. As regards the ultimate result in general who can say? We are certain that the more efficient the early treatment, the better is the ultimate outlook. To completely rid the body of the spirochætal infection is probably possible only early in the course of the infection. As regards the later lesions prognosis should always be guarded. To estimate the possible late dangers of a syphilitic infection is impossible.

Prophylaxis.—Irregular intercourse has existed from the beginning of recorded history, and unless man's nature wholly changes—and of this we can have no hope—will continue. Resisting all attempts at solution, the social evil remains a great blot upon our civilization, and inextricably blended with it is the question of the prevention of syphilis.

Personal purity is the prophylaxis which we, as physicians, are especially bound to advocate. Continence may be a hard condition (to some harder than to others), but it can be borne, and it is our duty to urge this lesson upon young and old who seek our advice in matters sexual. Certainly it is better, as St. Paul says, to marry than to burn, but if the former is not feasible there are other altars than those of Venus upon which a young man may light fires. He may practise at least two of the five means by which, as the physician Rondibilis counseled Panurge, carnal concupiscence may be cooled and quelled—hard work of body and hard work of mind. Idleness is the mother of lechery; and a young man will find that absorption in any pursuit will do much to cool passions which, though natural and proper, cannot in the exigencies of our civilization always obtain natural and proper gratification.

To carry out successfully any administrative measures seems hopeless, at any rate in our Anglo-Saxon civilization. The state accepts the responsibility of guarding citizens against small-pox or cholera, but in dealing with syphilis the problem has been too complex and has baffled solution. Inspection, segregation, and regulation are difficult, if not impossible, to carry out, and public sentiment is bitterly opposed to this plan. The compulsory registration of every case of gonorrhœa and syphilis, with greatly increased facilities for thorough treatment, offers a more acceptable alternative. With this goes the need of "follow-up" measures to ensure that treatment is carried out for a sufficient time. The need of care to prevent accidental infection should be emphasized to nurses and ever present in the minds of physicians.

The prevention of congenital syphilis is largely a matter of proper treatment of syphilitic women, especially when pregnant. Children born of parents who have had syphilis should be carefully examined and treated if necessary—sometimes on suspicion only.

The patient should be warned of the various ways in which he may spread the disease and given directions regarding this. Measures for the prevention of infection after exposure can be carried out in the military and naval services more efficiently than in civil life.

Treatment.—That the later stages which come under the charge of the physician are so common results, in great part, from the carelessness of the patient, who, wearied with treatment, cannot understand why he should continue to take treatment after all the symptoms have disappeared; but, in part, the profession also is to blame for not insisting more urgently that acquired syphilis is not cured in a few months, but takes at least three years, during which time the patient should be under careful supervision.

The patient should lead a regular life, avoiding excess of all kinds. If there is fever rest in bed is advisable. The usual diet can be taken and the patient should drink large quantities of water. The use of alcohol and tobacco should be forbidden during active treatment. When mercury is being taken special care must be given to the mouth, a mouth wash and a potassium chlorate tooth paste being used frequently. Treatment to rid the body of spirochaetes consists in the use of mercury and arsenic preparations; iodide of potassium influences certain of the tissue changes resulting from the infection.

Energetic treatment in the acute stages should be started as soon as the diagnosis is made. The object is to kill the spirochaetes as rapidly as possible and the treatment should be intensive in the hope of completely ridding the body of them. Mild treatment may result in a resistant strain of spirochaetes; mercury by mouth alone is not a proper method. There is no agreement as to the best method and many variations are employed; it is advisable to use both arsenic and mercury. Some give them alternately; others use arsenic preparations at short intervals for a time and then a full course of mercury. The main thing is to carry on *active* treatment.

ARSENIC.—The arsenic preparation (dioxidyamido-arsenobenzol) is given various names; the terms arsphenamine and neo-arsphenamine are used here. In the primary and secondary stages it is well to begin with arsphenamine an initial full dose being 0.5 or 0.6 gm. intravenously. It should be given well diluted (50 c. c. for each 0.1 gm. of the drug) and always in a freshly prepared solution. It is usually injected into one of the veins at the elbow, care being taken to be sure that the needle is in the vein and some salt solution being run in first. It is well to keep the patient in bed until the following morning. The frequency of repetition varies but a usual interval is five days. A course of six to eight injections is given. After this a complete course of mercury is given by inunction or injection. Another method is to give a full dose of arsphenamine, then a vigorous course of mercury for two or three weeks, then another full dose of arsphenamine, and mercury again, this being carried on for a period of three or four months. Whichever method is chosen, after a period of vigorous treatment an interval of four weeks may pass without any treatment and then the complement fixation test is tried. If this is

negative it should be taken every three months for a year, and if all are negative, the infection is probably cured. If the reaction is positive, the treatment should be resumed until it is negative. The Wassermann or Kahn test should be used as a guide to treatment throughout in the acute stages.

Many things influence the dose of arsphenamine. In general the weight of the patient is a good guide. For young children doses of 0.1 to 0.15 gm. are used and for infants 0.02 to 0.1 gm. Changes in the eye grounds and severe circulatory and renal lesions always suggest caution and may be contra-indications. In such cases doses of 0.2 gm. are the usual maximum. In general the dose of neo-arsphenamine may be considered as slightly less than double that of arsphenamine. Many modifications of the original preparation have been introduced. Sulpharsphenamine has the advantage of intramuscular injection. Bismuth preparations are of distinct value in some conditions and some use them in preference to mercury.

The conditions in which arsphenamine is especially useful are: (1) When an early diagnosis is made, (2) in patients with severe skin or mucous membrane lesions, (3) in intractable cases in those resistant to or unable to take mercury, (4) in malignant cases, (5) in congenital syphilis, and (6) in latent cases, in which without any signs of syphilis a Wassermann reaction is present. In visceral syphilis the drug is less useful. Its value in tabes dorsalis and paresis varies, but some patients are undoubtedly benefited. The earlier in the course of syphilis the drug is given the better the effect. Mercury should always be given after arsphenamine which, except in a few cases given early, can not be regarded as a complete remedy in itself.

MERCURY.—It is well to push the drug so that the patient is brought under its influence as rapidly as possible; salivation is to be avoided. Mercury should be used very cautiously if there is nephritis. *Inunction* is the most effective means of administration. One-half to a dram (2-4 gm.) of mercurial ointment or oleate of mercury is thoroughly rubbed into the skin, on areas free from hair, daily for six days; on the seventh a warm bath is taken. It is well to apply the ointment to different places on successive days. The sides of the chest and abdomen and the inner surfaces of the arms and thighs are the best positions. Thirty inunctions is an average number for each course. *Intramuscular* injection is also satisfactory, care being taken to avoid infection and to give the injections deeply. Mercury salicylate (gr. i-ii, 0.06-0.12 gm.) in a 10 per cent. solution is probably the best, an injection being given every five to seven days. Bichloride of mercury (gr. 1/20-1/10, 0.003-0.006 gm.) in olive oil and biniodide of mercury (gr. 1/6, 0.01 gm.), are also used. A course of twenty to thirty injections should be given. *Intravenous* injections are sometimes given, usually of the bichloride (℥ xv, 1 c. c. of a 0.1 to 0.2 per cent solution in sterile salt solution). By *mouth* the gray powder, hydrargyrum cum creta in one grain (0.065 gm.) doses with a grain of Dover's powder, may be given. The bichloride (gr. 1/16-1/8, 0.004-0.008 gm.), the biniodide (gr. 1/16, 0.004 gm.) and the protoiodide (gr. 1/4, 0.016 gm.) may also be used. It is well for the profession not to forget that mercury is still in existence; some men seem to have forgotten it.

The Wassermann reaction should be tried twice a year for three years and active treatment resumed if it is positive. No one can be regarded as free

of the disease from a negative blood test alone; the spinal fluid should be studied also. In the later stages it is well to follow much the same general course, as a rule giving treatment intensively for certain periods, with a rest between. While the Wassermann reaction is a helpful guide in treatment it is not always possible to secure a negative reaction. If mercury by mouth and the "mixed" treatment are used, it should be only after a thorough course by inunction or injection. These have their place in the intervals between or after more intensive treatment.

In CONGENITAL SYPHILIS the treatment of patients born with bullæ and other signs of the disease is not satisfactory, and the infants usually die within a short time. The child should be nursed by the mother alone, or, if this is not feasible, should be hand-fed, but under no circumstances should a wet-nurse be employed. Arsphenamine is generally useful. The child is most rapidly and thoroughly brought under the influence of mercury by inunction. The mercurial ointment may be smeared on the flannel binder. This is not a very cleanly method, and sometimes rouses the suspicion of the mother. The drug may be given by mouth, in the form of gray powder, half a grain (0.03 gm.) three times a day. In the late manifestations associated with bone lesions the combination of mercury and iodide of potassium is suitable and is well given in the form of Gilbert's syrup, which consists of biniodide of mercury (gr. j, 0.065 gm.), of potassium iodide (℥ss, 15 gm.), and water (℥ij, 60 c. c.). Of this the dose for a child under three is from five to ten drops three times a day, gradually increased. Under these measures the cases of congenital syphilis usually improve with great rapidity. The medication should be continued at intervals for many months, and it is well to watch these patients carefully during the period of second dentition and at puberty, and give them treatment again.

In the treatment of the VISCERAL LESIONS, iodide of potassium is of great value. The iodide saturates the unsaturated fatty acid radicals which inhibit autolysis. The ferments then become active, autolysis follows and the necrotic tissue is absorbed. Under its use ulcers rapidly heal, gummatous tumors melt away, and we have an illustration of a specific action only equaled by that of mercury or arsenic in the secondary stages and by quinine in malaria. It is as a rule well borne in an initial dose of 10 grains (0.6 gm.); given in milk the patient does not notice the taste. It should be gradually increased to 30 or more grains three times a day. In syphilis of the nervous system it may be used in still larger doses. For neurosyphilis, tryparsamide and fever therapy (as by malaria) probably give the best results.

For hepatic syphilis the combination of mercury and iodide of potassium is most satisfactory; arsenic should not be given. If there is ascites, Addison's or Guy's pill (as it is often called) of mercury, digitalis, and squill will be found very useful. Occasionally the iodide of sodium is more satisfactory than the potassium salt. It is less depressing and agrees better with the stomach.

Syphilis and Marriage.—Upon this question the family physician is often called to decide. He should insist upon the necessity of at least three years elapsing between the infection and the contracting of marriage. This is the earliest possible limit, and marriage should be allowed only if the

treatment has been thorough, at least two years have passed without any manifestations, and the serological test is negative in the blood and spinal fluid.

Syphilis and Life Insurance.—An individual with syphilis can not be regarded as a first-class risk unless he can furnish evidence of prolonged and thorough treatment and of immunity for two or three years from all manifestations. Even then, when we consider the extraordinary frequency of the cerebral and vascular complications in persons who have undergone thorough treatment, the risk to the company is certainly increased.

Yaws (*Frambæsia*).—This is a disease much like syphilis, prevalent in Africa, parts of Asia, the West Indies and tropical America, caused by *Treponema pertenue* (*Spirochæta pertenuis* or *pallidula*). The disease may have been present and unrecognized in the Southern States. It is particularly a disease of children and is readily communicated from one to another. The primary lesion is a papule which later shows a fungoid appearance; in the secondary stage similar lesions develop generally. The skin lesions consist of raspberry-like growths from which a sero-purulent fluid exudes, or they are covered by a yellow crust. The secondary general eruption has the same character and is widespread. The mucous membranes are not involved. There may be fever, headache and general malaise. The course is from a few months to three years. Late lesions, such as gummatous nodules and deep ulceration, may occur. The mortality is low. Arsphenamine is specific and its use results in a rapid cure, usually after one injection. Bismuth preparations and sulpharsphenamine are also effectual.

IX. SPIROCHÆTOSIS ICTERO-HÆMORRHAGICA

An acute disease, due to a spirochæte, characterized by jaundice and occasionally by hæmorrhages or purpura. This infection was first discovered in Japan in 1914 by Inada and Ido. It occurred during the Great War in various areas and was extensively studied. The organism is *Spirochæta ictero-hæmorrhagica*, which is found in rats, the infection possibly occurring by contamination of earth and water by their urine. It appears to be a disease of temperate climates.

Pathology.—Death apparently results from toxæmia, and changes sufficient to cause death are not found in the organs, except in a few cases showing acute yellow atrophy of the liver. Marked duodenitis has been found in some cases. Nephritis with hæmorrhagic and degenerative changes may be present. This is probably associated with the finding of the spirochætes in the urine.

Symptoms.—The onset is usually acute with chills, headache, general pains, vomiting, diarrhœa and marked prostration. Fever follows, reaching 102° or higher. *Jaundice* appears about the fourth day, reaching its maximum about the tenth day, and may be intense. In some cases it does not appear. The stools are usually clay-colored. The liver is enlarged and there is tenderness in the upper abdomen. The spleen is not enlarged. Herpes is common and often becomes hæmorrhagic. There may be other hæmor-

rhagic features, bleeding from the mucous membranes or purpura. Acute bronchitis is common; the pulse rate may be slow in proportion to the fever. *Myositis* is common, the muscles being tender and sometimes swollen. Nephritis has occurred in some series with marked renal insufficiency. The course varies; the fever persists for about ten days; the jaundice usually lessens as the fever diminishes. The *mortality* is high in Japan, 30 per cent., but in some of the army series only 4 or 5 per cent.

Diagnosis.—The spirochætes are found in the blood for the first five or seven days. They may be found on examination or the infection may be conveyed to guinea-pigs by the intraperitoneal injection of blood. The guinea-pig is very susceptible; a severe infection results and the spirochætes are easily demonstrated. Spirochætes are found in the patient's urine after the tenth day and sometimes for weeks. They are agglutinated by the patient's blood after the second week. From other forms of infectious jaundice the marked features of this form, the presence of spirochætes and the agglutination test are diagnostic.

Treatment.—Rest, fluid diet, water freely, alkalies and open bowels by salines and enemata comprise the general management. The giving of neo-arsphenamine has not proved of value.

X. RAT-BITE FEVER

An infection, following rat-bite, characterized by febrile paroxysms which may recur at intervals for months.

The disease has been known in China and Japan for several centuries. The features are very unusual. There is a prolonged period of incubation, lasting in some cases for many months. The wound, which has run the ordinary course and perhaps healed, becomes swollen, red, and eroded; an ulcer forms and the regional lymph-glands are involved. The fever sets in suddenly with a chill and lasts three or four days. With its onset there is a skin rash, either erythema or a blotchy eruption somewhat resembling measles. The patient feels very ill, there may be pains in the muscles and joints and sometimes delirium. After persisting for a few days, usually seven or eight, the temperature falls and the patient feels well. After a varying interval of from a few days to a couple of weeks the attack is repeated, and this may go on for several months or, according to the Japanese reports, for several years. The intervals may be very regular in a given case. The outlook is favorable; the mortality is highest in Japan, 10 per cent.

Various organisms have been described but the weight of evidence is in favor of *Spirillum minus* being the causal agent. Its exact nature is in dispute. Patients recovered after treatment by mercury or arsphenamine. Schotmüller, Blake and Tileston each found a streptothrix in their cases. In Tileston's case the organisms were found in fresh smears by dark-field illumination. Blake isolated a streptothrix in a case which at autopsy showed endocarditis, in the vegetations of which the same organism was found.

TREATMENT.—The wound should be cauterized, arsphenamine or one of its derivatives given intravenously, and the febrile paroxysms treated symptomatically.

XI. DISEASES DUE TO PARASITIC INFUSORIA

Flagellate Dysentery.—Several varieties of flagellates may cause disease. The main features are recurrent attacks of colic and diarrhoea, the passage of mucus and sometimes blood, tenderness of the bowel, sometimes leucocytosis and eosinophilia, and neurasthenia. Mucus passed from the bowel may contain large numbers of flagellates. Cases of infection with several flagellates are common. In treatment, liquid diet should be given, the bowels moved freely, and a course of thymol given, followed by irrigation of the colon with weak solutions of quinine. Later, bismuth iodide (gr. i, 0.06 gm.) is given once a day and the dose increased to gr. ii (0.12 gm.).

Trichomonas confusa lives in the large intestine, and is met with in the stools under all sorts of conditions. Freund from Dock's clinic reported a series of cases which show that the parasite may cause acute and chronic diarrhoea with severe abdominal pain, and anatomically an acute enteritis. In one of Dock's cases the parasites were associated with a hæmorrhagic cystitis without bacteria.

Giardia lamblia was a frequent cause of enteritis during the recent war. The onset was often insidious and the condition tended to become chronic. The general condition of the patient was markedly affected. It is often found in the duodenum and gall-bladder. Flagellates have been found in the expectoration in cases of gangrene of the lung and of bronchiectasis, and in the exudate of pleurisy. Mercurochrome in enteric coated capsules, gr. $1\frac{1}{2}$ -iii (0.1-0.2 gm.), is given three times daily for two weeks.

Ciliate Dysentery.—*Balantidium coli*, oval, 70 μ to 100 μ long and 50 μ to 70 μ broad, may be pathogenic. The parasites are found in the stools and on the mucous membrane, and also in the mucosa and submucosa. Apparently they do not extend beyond the wall of the bowel. They cause diarrhoea and dysentery and anæmia may result. In *treatment* good results are reported from oil of chenopodium, 15 c. c. in 150 c. c. of olive oil, introduced into the bowel with the patient in the knee-chest position and retained for two hours.

D. DISEASES DUE TO METAZOAN PARASITES

I. DISEASES DUE TO FLUKES—DISTOMATOSIS

The Trematoda or flukes are parasitic platyhelminths, usually with flattened or leaf-shaped bodies. The term *Distomatosis* (*Distomiasis*) is based upon Distoma, the term being used to designate the trematodes.

The following are the important clinical forms:

1. Pulmonary Distomatosis; Parasitic Hæmoptysis.—*Paragonimus* (*Distoma*) *westermani*, the Asiatic lung or bronchial fluke, is from 8 to 16 mm. in length by 4 to 8 mm. broad, and of a pinkish or reddish-brown color.

It is found extensively in China and Japan, Formosa, and the Philippines; cases are occasionally imported into Europe and America, and have been met with in the oriental population of the Pacific coast. It has been found in the United States in the cat, dog, and hog.

Clinically the disease is characterized by a chronic cough, with rusty-brown sputum, and occasional attacks of hæmoptysis, usually trifling, but sometimes very severe. The disease is very apt to be mistaken for tuberculosis, but the diagnosis is easily made by microscopic examination of the sputum. The ova, which are abundant in the sputum, are oval, smooth, and measure from $80\ \mu$ to $100\ \mu$ in length by $40\ \mu$ to $60\ \mu$ in breadth. The parasites may affect other organs—the liver, the brain, and eyelid.

2. Hepatic Distomatosis.—Several species of liver flukes are known to occur in man. (1) The common liver fluke—*Fasciola hepatica*—is a common parasite in ruminants. It is a rare and accidental parasite in man, but in Syria a strange disease called *Halzoun* is caused by eating raw goat-liver infected with the parasite. (2) The lancet fluke—*Dicrocoelium lanceatum*. (3) *Opisthorchis felineus*, found in Prussia and Siberia, and by Ward in cats in Nebraska. (4) *Opisthorchis neverca*—the Indian liver fluke described in man by McConnell. (5) *Clonorchis sinensis* and *C. endemicus*, the most important of the liver flukes, occur extensively in Japan, China, and India. The eggs are oval, $27\ \mu$ to $30\ \mu$ by $15\ \mu$ to $17\ \mu$, dark brown, with sharply defined operculum. Imported cases have been found in Canada and the United States. White found 18 cases in San Francisco.

The *symptoms* of hepatic distomiasis are best described in connection with the last form. The following account is abstracted from Wallace Taylor. Young children are the chief sufferers. Many members of a family are usually affected. In some villages a large proportion of the inhabitants are attacked. Among important symptoms is an irregular, intermittent diarrhoea; at first there may or may not be blood. The liver enlarges and a condition of cirrhosis gradually comes on. There may be pain and an intermittent jaundice. There is not much fever. After lasting for two or three years dropsy comes on, with anasarca and ascites. Even then transient recovery may take place, but as a rule there is a recurrence, and the patient dies after many years of illness. The ova of the parasite are readily found in the stools.

3. Intestinal Distomatosis.—In India and China the *Fasciolopsis buskii* has been found in a number of cases in the small intestines. A progressive anæmia, weakness, diarrhoea, œdema and ascites are the main clinical features. Calomel with thymol or beta-naphthol has been used in treatment.

4. Hæmic Distomatosis; Bilharziasis.—This is an important parasitic disease, caused by the flood fluke, *Schistosoma hæmatobium* (*Bilharzia hæmatobia*). Endemic hæmaturia has been known for many years, particularly in Egypt, where in 1851 Bilharz discovered the parasite of the disease. It prevails in South and North Africa, particularly the latter, in Arabia, Persia, India, China, Japan, the West Indies and South America. Imported cases are found in Europe, and occasionally in the United States. In Egypt, among 11,698 patients admitted to the Cairo Hospital, 1,270 were infected, practically 10 per cent. (Madden). Of 500 autopsies at the same hospital, in 8 per cent. death was due to the effects of Bilharzial disease. The seriousness of the condition in Egypt is illustrated by the fact that in 7.5 per cent. of army recruits the ova are found in the urine.

Other forms are *Schistosoma mansoni*, found in the veins, and *S. japonicum* found in the blood vessels and intestine.

The *parasite* has the sexes separate, and the male usually carries the

female in a gynæcophorous canal. The eggs are characteristic, oval in shape, 0.16 mm. by 0.06 mm., and one end has a terminal spine. The eggs hatch in water, and emerging from the terminal spined egg the miracidium enters the liver of a snail and becomes transformed into sporocysts and daughter sporocysts, in which numbers of cercariæ develop. These escape into the water, penetrate the skin of man, travel to the portal veins and liver, where in six to ten weeks they mature to adult trematodes. They travel to various parts of the body, particularly to the veins of the bladder and rectum, and produce the terminal spined eggs which escape with the urine. A majority of the parasites remain in the tissues and cause irritation, fibroid changes, and papillomata in the bladder and rectum. Collecting in the bladder as foreign bodies they form the nuclei of calculi.

Symptoms.—As is so often the case with animal parasites, they may cause no inconvenience. Irritability of the bladder, dull pain in the perineum, and hæmaturia are the most frequent symptoms. A chronic cystitis follows when the walls of the bladder are much thickened by the irritation caused by the ova. The anæmia caused by the hæmorrhage is slight in comparison with that of uncinariasis. When the rectum is involved there are straining and tenesmus, with the passage of mucus and blood; in severe cases large papillomata form and a chronic ulcerative proctitis. There may be a chronic vaginitis. Calculi form in the kidney and bladder and periurethral abscess and perineal fistulæ are common in chronic cases.

Few symptoms are caused by the presence of the parasites in the portal veins, but there may be an advanced *cirrhosis* of a Glissonian type due to an enormous thickening of the periportal tissues (Symmers). This author has also reported an instance of the Bilharzia in the pulmonary blood in a case of Bilharzial colitis, and the worms were found living in the pulmonary circulation. The *diagnosis* is made by finding the characteristic ova in the bloody urine or in the blood and mucus from the rectum.

Schistosoma mansoni involves the rectum especially. After a period of abdominal symptoms with eosinophilia, dysentery appears with hepatic and pancreatic cirrhosis and splenomegaly. The rectal mucous membrane becomes very vascular with soft growth formation. Prolapse of the rectum is common and septic infection may result.

Schistosoma japonicum.—In China, Japan and the Philippines there is a disease characterized by cirrhosis of the liver, splenomegaly, ascites, dysentery, progressive anæmia, and sometimes by focalized epilepsy. Dermatitis and angio-neurotic œdema may occur. It occurs extensively in one district of Japan, and is known as the "Katayama" disease. The so-called urticarial fever, not very uncommon in China and Japan, seems to be associated with the presence of this parasite, and an eosinophilia with fever and urticaria should lead to a careful examination of the stools for its eggs. The parasite lives in the intestinal wall; the ova are smaller than those of *S. hæmatobium*, and have not the characteristic spine. The parasite develops in a snail and the disease is acquired by working in wet rice fields.

Treatment.—Antimony is the most successful remedy. Potassium or sodium antimony tartrate is given in doses of gr. $\frac{1}{2}$ (0.03 gm.) intravenously, increased to gr. iii (0.2 gm.), every two or three days until a total of 30 grains is given. Emetine has been used as in amœbic dysentery.

II. DISEASES CAUSED BY CESTODES—TÆNIASIS

Man harbors the adult parasites in the small intestine, the larval forms in the muscles and solid organs.

1. INTESTINAL CESTODES; TAPEWORMS

Tænia solium (Pork Tapeworm).—This is not a common form in the United States and is more frequent in parts of Europe and Asia. When mature it is from 6 to 12 feet in length. The head is small, round, not so large as the head of a pin, and provided with four sucking disks and a double row of hooklets; hence it is called, in contradistinction to the other form in man, the *armed* tapeworm. To the head succeeds a narrow, thread-like neck, then the segments, or proglottides, which possess both male and female generative organs; at about the four-hundred-and-fiftieth they become mature and contain ripe ova. The worm attains its full growth in from three to three and a half months, after which time the segments are continuously shed and appear in the stools. The segments are about 1 cm. in length and from 7 to 8 mm. in breadth. Pressed between glass plates the uterus is seen as a median stem with about eight to fourteen lateral branches. There are many thousands of ova in each ripe segment, and each ovum consists of a firm shell, inside of which is a little embryo, provided with six hooklets. The segments are continuously passed, and if the ova are to attain further development they must be taken into the stomach of a pig or of man. The shells are digested, the six-hooked embryos become free, and by the vessels reach various parts of the body (the liver, muscles, brain, or eye), where they develop into the larvæ or cysticerci. A hog under these circumstances is said to be *measled*, and the cysticerci are spoken of as measles or bladder worms.

Tænia solium received its name because it was thought to exist as a solitary parasite in the bowel, but two or more worms may occur.

Tænia saginata or mediocanellata (Unarmed, Fat, or Beef Tapeworm).—This is a longer and larger parasite than *Tænia solium*. It is certainly the common tapeworm of North America. It may attain a length of 15 or 20 feet, or more. The head is large in comparison with that of *Tænia solium*, and measures over 2 mm. in breadth. It is square-shaped and provided with four large sucking disks, but there are no hooklets. The ripe segments are from 17 to 18 mm. in length and from 8 to 10 mm. in breadth. The uterus consists of a median stem with from fifteen to thirty-five lateral branches, which are given off more dichotomously than in *T. solium*. The ova are somewhat larger and the shell thicker, but the two forms can scarcely be distinguished by their ova. The ripe segments are passed as in *T. solium*, and are ingested by cattle, in the flesh or organs of which the eggs develop into the bladder worms or cysticerci.

Of other forms of tapeworm may be mentioned:

Dipylidium caninum.—A small parasite common in the dog and occasionally found in man; the larvæ develop in the lice and fleas of the dog.

Hymenolepis diminuta.—This small cestode was found in the intestine of a child in Boston, and has since been met with in twelve cases (Ransom). It is common in rats. The larvæ develop in moths and beetles.

Hymenolepis nana is not infrequent in Italy and not very uncommon in the United States (Stiles). *Davainea madagascariensis* occurs in rare instances only.

Diphyllobothrium latum (Broad Tapeworm).—This is widely distributed in fresh-water fish, especially in northern Europe. It has become an established parasite in certain lakes of the North West in the United States and Canada, especially in pike and the fish known as wall-eyes. Dogs are infected frequently from eating fish. The parasite is large and long, measuring from 25 to 30 feet or more. Its head is different from that of the *tænia*, as it possesses two lateral grooves or pits and has no hooklets. The larvæ develop in the peritoneum and muscles of the infected fish, and grow into the adult worm when eaten by man. Infection is common in children.

Symptoms.—The parasites are found at all ages, are not uncommon in children and are occasionally found in sucklings. W. T. Plant refers to a number of cases in children under two years, and there is one in the literature in which it is stated that a tapeworm was found in an infant five days old!

The parasites may cause no disturbance and are rarely dangerous. A knowledge of the existence of the worm is generally a source of worry and anxiety; the patient may have considerable distress and complain of abdominal pains, nausea, diarrhœa, and sometimes anæmia. Occasionally the appetite is ravenous. In nervous patients the constitutional disturbance may be considerable with marked mental depression. Various nervous phenomena, such as convulsions, are believed to be caused by the parasites. Such effects, however, are very rare. *T. saginata* has been found in the gall-bladder. The *Diphyllobothrium* may cause a severe and even fatal form of anæmia and it has been suggested that the metabolic products of the worm may have a hæmolytic action. Eosinophilia may occur.

Diagnosis.—This is never doubtful as the presence of the segments is distinctive and the ova may be recognized in the stools. As regards the variety the ripe segments of *Tænia saginata* are larger and broader, and show differences in the generative system as already mentioned.

Prophylaxis.—This is most important and attention should be given to three points. First, all tapeworm segments should be burned and never be thrown into a water-closet or outside; secondly, careful inspection of meat; and, thirdly, cooking meat and fish sufficiently to kill the parasites.

In the case of the beef infection, the distribution of the parasites, as given by Ostertag, shows that the muscles of the jaw are much more frequently affected than other parts—360 times—while other organs were infected but 55 times. Sometimes the infection is general. Cold storage kills the cysticercus usually within three weeks. In handling *T. solium* special care should be taken to avoid the danger of cysticercosis.

In the examination of hogs for cysticerci “particular stress should be laid upon the tongue, the muscles of mastication, and the muscles of the shoulder, neck, and diaphragm” (Stiles). They may be seen very easily on the under surface of the tongue. American hogs are comparatively free. In Prussia one hog is infected in about every 637. Specimens have been found alive twenty-nine days after slaughtering. In the examination of 1,000 hogs in Montreal, 76 instances of cysticerci were found.

Treatment.—Three days should be given to preparation for whatever drug

is employed. For two days the patient should take soft food and the third day liquids only. The bowels should be well moved by a laxative each evening and a saline in the morning if necessary. Unless the bowels have moved freely an enema should be given. There are many drugs, but male fern is usually the most reliable, given in the form of oleoresin or ethereal extract. This is given early in the morning before any food is taken. The usual dose is 3i (4 c. c.), which is repeated in an hour. It may be given in capsules or in glycerine (3ss , 15 c. c.). If there is fear of nausea a cup of coffee may be taken before the drug. The drug may be given by the duodenal tube. After taking the male fern the patient should remain quiet and resist any desire to vomit. One hour after the second dose of male fern a full dose of saline is taken (magnesium or sodium sulphate, or magnesium citrate), and an hour later a second dose if the bowels have not moved. Castor oil should not be given. Great care should be taken during the expulsion of the worm, which should be passed into a chamber containing water at about the body temperature, a practice recommended by Celsus.

Pomegranate root is an efficient remedy, and may be given as an infusion of the bark, 3 ounces of which may be macerated in 10 ounces of water and reduced to one-half by evaporation. This is taken in divided doses. It occasionally produces colic, but is very effective. The active principle, pelletierine, is employed as the tannate, given in doses of 6 to 8 or even 10 grains (0.4 to 0.6 gm.), and followed in an hour by a purge.

Pumpkin seeds are sometimes efficient. Three or four ounces should be carefully bruised, macerated for twelve or fourteen hours, the entire quantity taken and followed in an hour by a purge. Of other remedies, cusso, naphthalein (gr. v , 0.3 gm.), and thymol (gr. v , 0.3 gm. daily for a week) may be mentioned. Sometimes a combination of remedies is effectual when one fails. In children the use of pumpkin seeds or pelletierine is generally best. One cause of failure is the use of drugs which are old and inert.

Unless the head is brought away, the parasite continues to grow, and within about three months the segments appear again. Some cases are extraordinarily obstinate. Doubtless much depends upon the exposure of the worm. The head and neck may be thoroughly protected beneath the valvulæ conniventes, in which case the remedies may not act. Owing to its armature *Tania solium* is more difficult to expel. It is probable that no degree of peristalsis can dislodge the head, and unless the worm is killed it does not let go its firm hold. Owing to the danger of cysticercosis, treatment should not be delayed in case of infection with *Tania solium*.

2. SOMATIC TÆNIASIS

Whereas adult tænia may give rise to little or no disturbance, and rarely, if ever, prove directly fatal, the affections caused by the larvæ or immature forms in the solid organs are serious. There are two chief cestode larvæ known to frequent man: (a) the *Cysticercus cellulosæ*, the larva of *Tania solium*, and (b) the *Echinococcus*, the larva of *Tania echinococcus*. Infection with bothriocephalid larvæ is infrequent.

Cysticercus Cellulosæ.—When man accidentally takes into his stomach the ripe ova of *T. solium* he is liable to become the intermediate host, a part

usually played by the pig. This may occur in an individual the subject of *T. solium*, in which case the mature proglottides wander into the stomach or are forced into the organ in attacks of vomiting. The accidental ingestion from the outside of a few ova is possible, and the liability of infection should always be borne in mind in handling the segments of the worm.

The *symptoms* depend entirely upon the number of ova ingested and the localities reached. In the hog the cysticerci produce very little disturbance. The muscles, the connective tissue, and the brain may be swarming with the "measles," as they are called, and yet the nutrition is maintained and the animal does not appear to be seriously incommoded. In the invasion period, if large numbers of the parasites are taken, there is, in all probability, constitutional disturbance; certainly this is seen in the calf, when fed with the ripe segments of *Tænia saginata*.

In man a few cysticerci lodged beneath the skin or in the muscles give no trouble, and in time the larvæ die and become calcified. They are occasionally found in dissection subjects or in post mortems as ovoid white bodies in the muscles or subcutaneous tissue. In America they are very rare. We have seen but two instances in post mortem experience. The symptoms may be grouped into general, cerebro-spinal, and ocular. In 155 cases compiled by Stiles, the parasite in 117 was found in the brain, in 32 in the muscles, in 9 in the heart, in 3 in the lungs, subcutaneously in 5, in the liver in 2.

1. GENERAL.—As a rule the invasion of the larvæ in man, unless in very large numbers, does not cause very definite symptoms but occasionally a striking picture is produced. A patient was admitted very stiff and helpless, so much so that he had to be assisted into bed. He complained of numbness and tingling in the extremities and general weakness, so that at first he was thought to have a peripheral neuritis. On examination, however, a number of painful subcutaneous nodules were discovered, which proved on excision to be cysticerci. Altogether 75 could be felt subcutaneously, and from the soreness and stiffness they probably existed in large numbers in the muscles. There were none in his eyes and he had no brain symptoms.

2. CEREBRO-SPINAL.—Remarkable symptoms may result from the presence of the cysticerci in the brain and cord. In the silent region they may be abundant without producing any symptoms. In the ventricles of the brain the cysticerci may attain a considerable size, owing to the fact that in regions in which they are unrestrained in their growth, as in the peritoneum, the bladder-like body grows freely. When in the fourth ventricle remarkable irritative symptoms may be produced. In 1884 the senior author saw with Friedländer in Berlin a case from Riess's wards in which during life there had been symptoms of diabetes and anomalous nervous symptoms. Post mortem, the cysticercus was found beneath the valve of Vieussens, pressing upon the floor of the fourth ventricle.

3. OCULAR.—Since von Graefe demonstrated the presence of the cysticercus in the vitreous humor many cases have been placed on record, as it is a condition easily recognized.

Except in the eye, the diagnosis can rarely be made; when the cysticerci are subcutaneous one may be excised. It is possible that when numerous throughout the muscles they may be seen under the tongue, in which situation they may exist in the pig in numbers.

Echinococcus or Hydatid Disease.—The hydatid worms or echinococci are the larvæ of *Tænia echinococcus* of the dog. This is not more than 4 or 5 mm. in length, consisting of only three or four segments, of which the terminal one alone is mature, and has a length of about 2 mm. and a breadth of 0.6 mm. The head is small and provided with four sucking disks and a rostellum with a double row of hooklets. This is an exceedingly rare parasite in the dog. Cobbold states that he never found a natural specimen in England. Leidy had not one in his large collection; Curtice, of Washington, found it once in an American dog. The worms are so small that they are readily overlooked, since they form small, threadlike bodies closely adherent among the villi of the small intestines. The ripe segment contains about 5,000 eggs, which attain their development in the solid organs of various animals, particularly the hog and ox, more rarely the horse and the sheep. Man may be an intermediate host, owing to accidental ingestion of the ova.

DEVELOPMENT.—The little six-hooked embryo, freed from the egg-shell by digestion, burrows through the intestinal wall and reaches the lymphatic vessels or the veins; it may enter the portal vessels and be carried to the liver. It may enter the systemic vessels, and, passing the pulmonary capillaries, as it is protoplasmic and elastic, may reach the brain or other parts. It then undergoes the following changes: The hooklets disappear and the little embryo is gradually converted into a small cyst which presents two distinct layers—an external, laminated, cuticular membrane or capsule, and an internal, granular, parenchymatous layer, the endocyst. The cyst contains a clear fluid. There is more or less reaction in the neighboring tissues, and the cyst in time has a fibrous investment. When this primary cyst has attained a certain size, buds develop from the parenchymatous layer, which are gradually converted into cysts, presenting a structure identical with that of the original cyst, namely, an elastic chitinous membrane lined with a granular parenchymatous layer. These secondary or daughter cysts are at first connected with the lining membrane of the primary cyst, but are soon set free. In this way the parent cyst as it grows may contain a dozen or more daughter cysts. Inside these daughter cysts a similar process may occur, and from buds in the walls granddaughter cysts are developed. From the granular layer of the cysts buds arise which develop into brood capsules. From the lining membrane the little outgrowths arise and gradually develop into bodies known as scolices, which represent in reality the head of the *T. echinococcus* and present four sucking disks and a circle of hooklets. Each scolex is capable when transferred to the intestines of a dog of developing into an adult tapeworm. The difference between the ovum of an ordinary tapeworm, such as *T. solium*, and *T. echinococcus* is in this way very striking. In the former case the ovum develops into a single larva—*Cysticercus cellulosa*—whereas the egg of *T. echinococcus* develops into a cyst which is capable of multiplying enormously and from the lining membrane of which hundreds of larval tapeworms develop. Ordinarily in man the development of the echinococcus takes place as above mentioned and by an endogenous form in which the secondary and tertiary cysts are contained within the primary; but in animals the formation may be different, as the buds from the primary cyst penetrate between the layers and develop externally, forming the exogenous variety. A third form is the multilocular echinococcus, in which form the primary cyst buds are cut off completely and

surrounded by thick capsules of a connective tissue, which join together and ultimately form a hard mass represented by strands of connective tissue inclosing alveolar spaces about the size of peas or a little larger. In these spaces are found the remnants of the echinococcus cyst, occasionally the scolices or hooklets, but they are often sterile.

The fluid is limpid, non-albuminous; specific gravity 1.005 to 1.009, occasionally higher. It may contain chlorides, sugar and succinic acid, and, after repeated tapping of the cyst, albumin. When not degenerated the hydatid heads or the characteristic hooklets are found in the contents of the cyst.

CHANGES IN THE CYST.—The echinococcus may remain alive, probably many years, possibly as long as twenty years. The most common change is death with gradual inspissation of the contents and conversion of the cyst into a mass containing putty-like granular material which may be partially calcified. Remnants of the chitinous cyst wall or hooklets may be found. These obsolete hydatid cysts are not infrequently found in the liver. A more serious termination is rupture, which may take place into a serous sac, or perforation may take place externally when the cysts are discharged, as into the bronchi, alimentary canal or urinary passages. More unfavorable are the instances in which rupture occurs into the bile-passages or the inferior cava. Recovery may follow the rupture and discharge of the hydatids externally. Sudden death has been known to follow the rupture. A serious mode of termination is suppuration, which may occur spontaneously or follow rupture and is found most frequently in the liver.

GEOGRAPHICAL DISTRIBUTION.—The disease prevails most extensively in those countries in which man is brought into close contact with the dog, particularly when, as in Australia, the dogs are used for herding sheep, the animal in which the larval form of *T. echinococcus* is most often found. In Iceland the cases are numerous. In Europe the disease is not uncommon. In Great Britain it is rare, and a majority of the cases are in foreigners. Statistics of the prevalence of the disease in North America have been published by Osler (1882), Sommer (1895-'96), and Lyon (1902), who collected 241 cases. Of these, 136 cases were in foreigners; in 92 the nationality was not stated; 10 were negroes; 2 Canadians, and only 1 a native American. Fifty-six cases occurred in Manitoba, where there is a settlement of Icelanders, who brought the disease with them. The disease is not infrequent in the United States and appears to be increasing.

DISTRIBUTION IN THE BODY.—Of 1,634 cases in the statistics of Davaine, Böcker, Finsen, and Neisser, the parasite existed in the liver in 820; in the lung or pleura in 137; in the abdominal organs, including the kidneys, bladder, and genitalia, in 334; in the nervous system in 122; in the circulatory system in 42; in other organs 179. Of the 241 cases in Lyon's series in America the liver was the seat in 177, and the omentum, peritoneal cavity, and mesentery in 26. In 11 cases cysts were passed per rectum, in 7 cases cysts or hooklets were expectorated, and in 2 cases passed per urethram.

SYMPTOMS.—1. *Hydatids of the Liver*.—Small cysts may cause no disturbance; large and growing cysts produce signs of tumor of the liver with great increase in the size of the organ. Naturally the physical signs depend much upon the situation of the growth. Near the anterior surface in the epigastric region the tumor may form a distinct prominence and have a tense,

firm feeling, sometimes with fluctuation. A not infrequent situation is to the left of the suspensory ligament, the resulting tumor pushing up the heart and causing an extensive area of dulness in the lower sternal and left hypochondriac regions. In the right lobe, if the tumor is on the posterior surface, the enlargement of the organ is chiefly upward into the pleura and the vertical area of dulness in the posterior axillary line is increased. Superficial cysts may give what is known as the *hydatid fremitus*. If the tumor is palpated lightly with the fingers of the left hand and percussed at the same time with those of the right, there is felt a vibration or trembling movement which persists for a certain time. It is not always present, and it is doubtful whether it is peculiar to the hydatid tumors or due to the collision of the daughter cysts. Very large cysts are accompanied by feelings of pressure or dragging in the hepatic region, sometimes actual pain. The general condition of the patient is at first good and the nutrition little, if at all, interfered with. Unless some of the accidents already referred to occur, the symptoms may be trifling and due only to the pressure or weight of the tumor.

Historically, one of the most interesting cases is that of the first Lord Shaftesbury (Achitophel), who had a tumor below the costal border for many years. It suppurated and was opened by John Locke, his physician, who describes with great detail the escape of the bladder-like bodies. Among the Shaftesbury papers in the Record Office are several other cases collected by Locke; the disease may have been more common in England at that period.

Suppuration of the cyst changes the picture into one of *pyæmia*. There are rigors, sweats, more or less jaundice, and rapid loss of weight. Perforation may occur into the stomach, colon, pleura, bronchi, or externally, and in some instances recovery has taken place. Perforation has occurred into the pericardium and inferior vena cava; in the latter case the daughter cysts have been found in the heart, plugging the tricuspid orifice and pulmonary artery. Perforation of the bile-passages causes intense jaundice, and may lead to suppurative cholangitis.

An interesting symptom connected with the rupture of hydatid cysts is the occurrence of *urticaria*, which may also follow aspiration of the cysts. Brieger separated a highly toxic material from the fluid, and to it the symptoms of poisoning may be due.

Diagnosis.—Cysts of moderate size may exist without producing symptoms. Large multiple echinococci may cause great enlargement with irregularity of the outline, and such a condition persisting for any time with retention of the health and strength suggests hydatid disease. An irregular, painless enlargement, particularly in the left lobe, or the presence of a large, smooth, fluctuating tumor in the epigastric region is suggestive, and in this situation, when accessible to palpation, it gives a sensation of a smooth elastic growth and possibly also the hydatid tremor. When suppuration occurs the clinical picture is really that of abscess, and only the existence of previous enlargement of the liver with good health would point to the fact that the suppuration was associated with hydatids. *Syphilis* may produce irregular enlargement without much disturbance in the health, sometimes also a very definite tumor in the epigastric region, but this is usually firm and not fluctuating. The clinical features may simulate cancer very closely. In one case the liver was greatly enlarged and there were many nodular tumors in the

abdomen. The post mortem showed enormous suppurating hydatid cysts in the left lobe of the liver which had perforated the stomach in two places and also the duodenum. The omentum, mesentery, and pelvis also contained numerous cysts. As a rule, the course separates it clearly from cancer. Dilatation of the gall-bladder and hydronephrosis have been mistaken for hydatid disease. In the former the mobility of the tumor and its shape usually suffice for the diagnosis. In some instances of hydronephrosis the X-ray study and ureteral catheterization may be necessary. More frequent is the mistake of confounding a hydatid cyst of the right lobe pushing up the pleura with *pleural effusion* of the right side. The heart may be dislocated, the liver depressed, and dulness, feeble breathing, and diminished fremitus are present in both conditions. Frerichs lays stress upon the different character of the line of dulness; in *echinococcus* cyst the upper limit presents a curved line, the maximum of which is usually in the scapular region. Suppurative pleurisy may be caused by the perforation of the cyst. If adhesions result, the perforation takes place into the lung, and fragments of the cysts or small daughter cysts may be coughed up. For diagnosis the exploratory puncture should be used and the fluid is usually characteristic. Hooklets may be found in the clear fluid or in the suppurating cysts. They are sometimes absent, however, as the cyst may be sterile. The complement fixation test is of value.

2. *Respiratory System*.—Of 809 cases of single hydatid cyst collected by Thomas in Australia, the lung was affected in 134 cases. Of 241 American cases, in 16 the pleura or lung was affected. The larvæ may develop primarily in the pleura and attain a large size. The symptoms are at first those of compression of the lung and dislocation of the heart. The physical signs are those of fluid in the pleura. The line of dulness may be quite irregular. As in the *echinococcus* of the liver, the general condition may be excellent in spite of extensive disease. Pleurisy is rarely excited. The cysts may become inflamed and perforate the chest wall. Cary and Lyon analyzed 40 cases of primary *echinococcus* cyst of the pleura; death results in a majority of the cases from the toxæmia following the rupture and the absorption of the fluid or from the sepsis following suppuration.

Echinococci occur more frequently in the lung than in the pleura. If small, they may exist for some time without causing serious symptoms. In their growth they compress the lung and sooner or later lead to inflammatory processes, often to gangrene, and the formation of cavities which connect with the bronchi. Fragments of membrane or small cysts may be expectorated. Hæmorrhage is not infrequent. Perforation into the pleura with empyema is common. A majority of the cases are regarded as tuberculosis or gangrene, and it is only the detection of the characteristic membranes or hooklets which leads to the diagnosis. The X-ray study is of aid. Of a series of 21 cases, 17 recovered; 5 of the cases suppurated (C. H. Fleming, Victoria).

3. *Kidneys*.—In the collected statistics the *genito-urinary system* comes second as the seat of hydatid disease, though here the affection is rare in comparison with that of the liver. Of the 241 American cases, there were 17 in which the kidneys or bladder were involved. The kidney may be converted into an enormous cyst resembling a hydronephrosis. The diagnosis is only possible by puncture and examination of the fluid. The cyst may perforate into the pelvis of the kidney, and portions of the membrane or cysts

may be discharged with the urine, sometimes producing renal colic. In one case for many months the patient passed at intervals numbers of small cysts with the urine. The general health was little disturbed, except by the attacks of colic during the passage of the parasites.

4. *Nervous System*.—The common cystic disease of the choroidal plexuses has been mistaken for hydatids. Davies Thomas, of Australia, tabulated 97 cases, including some of the *Cysticercus cellulosæ*. In his statistics, the cyst was more common on the right than on the left side, and more frequent in the cerebrum. The symptoms, very indefinite, as a rule are those of tumor. Persistent headache, convulsions, either limited or general, and gradually developing blindness have been prominent features in many cases.

Multilocular Echinococcus.—This merits a brief description, as it differs so remarkably from the usual type. It has been met with only in Bavaria, Württemberg, the adjacent districts of Switzerland, and in the Tyrol. In the United States a few cases have been described, chiefly in Germans. Delafield and Prudden's patient had lived there five years, and for a year before his death had been jaundiced. A fluctuating tumor was found in the right flank, apparently connected with the liver. This was opened, and death followed from hæmorrhage. In Oertel's case the patient had lived there ten years. He was deeply jaundiced, and had a tumor mass at the right border of the liver, which was enlarged. Bacon resected a cyst from the left lobe of the liver. The primary tumor presents irregularly formed cavities separated from each other by strands of connective tissue, and lined with the echinococcus membrane. The cavities are filled with a gelatinous material, so that the tumor has very much the appearance of an alveolar colloid cancer. It is possible that a special form of *T. echinococcus* represents the adult type of this peculiar parasite. This form is almost exclusively confined to the liver, and the symptoms resemble those of tumor or cirrhosis. The liver is, as a rule, enlarged and smooth. Jaundice is common and the spleen is usually enlarged; there is progressive emaciation and toward the close hæmorrhages are common.

Treatment of Echinococcus Disease.—Medicines are of no avail. Post mortem reports show that in a considerable number of cases the parasite dies and the cyst becomes harmless. Operative measures should be resorted to when the cyst is large or troublesome. Aspiration has been successful but incision and evacuation of the cysts are to be preferred. Suppuration has followed the puncture. Injections into the sac should not be practised. Surgeons open and evacuate echinococcus cysts with great boldness, and the Australian records, which are the most important on this subject, show that recovery is the rule in a large proportion of the cases. Suppurative cysts in the liver should be treated as abscess. The treatment of hydatid disease has been greatly advanced by Australian surgeons.

Sparganum mansoni is the larval stage of *Diphyllbothrium mansoni* of dogs. It may occur in many parts of the body.

Sparganum proliferum was first found in Japan. One case was reported in Florida. The infection was generalized.

III. DISEASES CAUSED BY NEMATODES

1. ASCARIASIS

Ascaris lumbricoides, the most common human parasite, is found chiefly in children. The female is from 7 to 12 inches in length, the male from 4 to 8 inches. In form it is cylindrical, pointed at both ends, with a yellowish-brown, sometimes a slightly reddish color. Four longitudinal bands can be seen, and it is striated transversely. The ova, which are sometimes found in large numbers in the fæces, are small, brownish-red in color, elliptical, and have a very thick covering. They measure 0.075 mm. in length and 0.058 mm. in width. The life history has been demonstrated to be "direct"—i. e., without intermediate host. The ovum develops into a larva which is retained in the shell and in a month has reached the infective stage. If swallowed the larva is set free by the digestive juices, pierces the wall and passes to the liver and lungs. Here the larvæ escape from the capillaries, causing hæmorrhage, pass from the air sacs to the bronchi, travel up the trachea and are swallowed. In the intestine they grow to the adult form. Heavy infections in mice, and perhaps in pigs, cause pneumonia. In some cases of human infection there are respiratory tract symptoms due to the larvæ in the lungs which are 1-2.5 mm. in length. The mature parasite occupies the upper portion of the small intestine. Usually only a few are present, but occasionally they occur in enormous numbers. The migrations are peculiar. They may pass into the stomach, whence they may be ejected by vomiting, or they may crawl up the œsophagus and enter the pharynx, from which they may be withdrawn. A child in the smallpox department of the Montreal General Hospital withdrew in this way more than thirty round worms within a few weeks. In other instances the worm reaches the larynx, and has produced fatal asphyxia, or, passing into the trachea, caused gangrene of the lung. They may go through the Eustachian tube and appear at the external meatus. The worms have been found in the bile-ducts and gall-bladder. They have caused abscess of the liver in which they have been found. They have entered the pancreatic duct and caused acute pancreatitis. The bowel may be obstructed by a mass of the worms or in rare instances an ulcer may be perforated. Even the healthy bowel wall may be penetrated. They have passed through the body wall, especially at the umbilicus.

A peculiarly irritating substance, often evident to the sense of smell in handling specimens, is formed by the round worms and it is suggested that the nervous symptoms, sometimes resembling those of meningitis, are due to this. Chauffard, Marie, and Tauchon report a remarkable condition of fever, intestinal symptoms, foul breath, and intermittent diarrhœa with the presence of lumbricoides which they call typho-lumbricosis. The febrile condition may continue for a month or more. There may be eosinophilia to 25 to 30 per cent., and in some cases a marked anæmia. The question of the toxins produced by these parasites is an open one. A condition of "Ascaris Sensitization" has been described.

Symptoms.—A few parasites may cause no disturbance. In children many irritative symptoms are attributed to worms, such as restlessness, irrita-

bility, picking at the nose, grinding of the teeth, twitchings, or convulsions. The *diagnosis* is made by finding the worms or eggs in the stools.

Treatment.—It is well to give soft diet on the day previous and a dose of castor oil the night before treatment. *Santonin* is usually efficient given in the morning in doses of one grain (0.065 gm.) for a small child, and three to five grains (0.2 to 0.3 gm.) for an adult. One to two grains of calomel should be given with it. Three hours later a good dose of saline should be given. This should be done two mornings in succession and repeated in a week if worms or eggs are again passed. The occasional effects of santonin (yellow vision, vertigo) should be explained beforehand. Oil of chenopodium is useful in doses of 10 to 15 drops in an ounce of castor oil, followed in an hour by a second dose of castor oil. Carbon tetrachloride may be given in the morning (no food being allowed after 4 P. M. of the day before) in doses of 30 to 45 minims (2 to 3 c. c.) and followed by a purgative. If these are not effectual male fern or thymol may be given.

Oxyuriasis.—The worm, *Enterobius* (formerly *Oxyuris*) *vermicularis*, known as the pinworm or seatworm, lives in the small intestine when young and is often found in the appendix. The fertilized females wander to the colon and outside the anus. In females they may enter the vagina. The male measures about 4 mm. in length, the female about 10 mm. They produce great irritation and itching, particularly at night, symptoms which become intensely aggravated by their nocturnal migration. The worms may traverse the intestinal wall and reach the peritoneal cavity, where they may form verminous tubercles in Douglas's fossa or peri-rectal abscesses.

The patients become extremely restless and irritable, the sleep is often disturbed, and there may be loss of appetite and anæmia. Though most common in children, the parasite occurs at all ages.

The worm is readily detected in the fæces. Infection probably takes place through the water, or possibly through salads, such as lettuce and cresses.

Treatment.—Every care should be taken to avoid auto-infection or the infection of others, by care in cleansing the anus and perineum, and thorough washing of the hands after defecation. Auto-infection is often responsible for the persistence of the disease. Treatment must be directed to the removal of the worms both from the small intestine and rectum. *Santonin* and calomel are useful, given as in ascaris infection for several days. Thymol and naphthalein are also used. To remove the worms from the rectum injections are required which should be retained as long as possible; it is well to wash out the bowel before giving them and the injection need not be over six ounces. Cold solutions of salt and water, copper sulphate solution (1-2,500), glycerine, infusion of quassia (one ounce of quassia chips to a pint of water), or lime water may be employed and should be used daily for two weeks. For the itching, carbolated vaseline, gall and opium ointment, or menthol (5 per cent.) in vaseline may be employed.

2. TRICHINIASIS

The *Trichinella spiralis* in its adult condition lives in the small intestine. The disease is produced by the embryos, which pass from the intestines and reach the voluntary muscles, where they finally become encapsulated larvæ—

muscle trichinae. It is in the migration of the embryos (possibly from poisons produced by them) that the symptoms are produced.

The ovoid cysts were described in human muscle by Tiedemann in 1822, and by Hilton in 1832; the parasite was figured and named by Richard Owen. Leidy in 1845 described it in the pig. For a long time the trichina was looked upon as a pathological curiosity; but in 1860 Zenker discovered in a girl in the Dresden Hospital both the intestinal and muscle forms, and established their connection with a serious and often fatal disease.

Description of the Parasites.—(a) Adult or intestinal form. The female measures from 3 to 4 mm.; the male, 1.5 mm., and has two little projections from the hinder end. (b) The larva or muscle trichina is from 0.6 to 1 mm. in length and lies coiled in an ovoid capsule, which is at first translucent, but subsequently opaque and infiltrated with lime salts. The worm presents a pointed head and a somewhat rounded tail.

When flesh containing the trichinae is eaten by man or by any animal in which the development can take place, the capsules are digested and the trichinae set free. They pass into the small intestine, and about the third day attain their full growth and become sexually mature. On the sixth or seventh day the embryos are fully developed. The young produced by each female trichina have been estimated at several hundred. Leuckart thought that various broods are developed in succession, and that as many as a thousand embryos may be produced by a single worm. The time from the ingestion of the flesh containing the muscle trichinae to the development of the brood of embryos in the intestines is from seven to nine days. The female worm penetrates the intestinal wall and the embryos are probably discharged directly into the lymph spaces, thence into the venous system, and by the blood stream to the muscles, which constitute their seat of election. J. Y. Graham gives strong arguments in favor of the transmission through the blood stream. They have been found in the blood early in the infection and since the demonstration of their presence by Herrick and Janeway have been seen by a number of observers. They are found also in the spinal fluid in some cases. They have occurred in the fluid of a pleural exudate, in the milk of a nursing woman and in the pus from a furuncle. After a preliminary migration in the inter-muscular connective tissue they penetrate the primitive muscle-fibres, and in about two weeks develop into the full-grown muscle form. In this process an interstitial myositis is excited and gradually an ovoid capsule develops about the parasite. Two, occasionally three or four, worms may be seen within a single capsule. This process of encapsulation has been estimated to take about six weeks. Within the muscles the parasites do not undergo further change. Gradually the capsule becomes thicker, and ultimately lime salts are deposited within it. This change may take place in man within four or five months. In the hog it may be deferred for many years. The calcification renders the cyst visible, and these small, opaque, oat-shaped bodies are familiar objects to demonstrators of anatomy. The trichinae may live within the muscles for an indefinite period and have been found alive and capable of developing even twenty-five years after their entrance into the system. In many instances, however, the worms are completely calcified. The trichina has been found or "raised" in twenty-six different species of animals (Stiles). Medical literature abounds in references

to its presence in fish, earthworms, etc., but these parasites belong to other genera. In faecal examinations for the parasite it is well to remember that the "cell body" of the anterior portion of the intestine is a diagnostic criterion of the *T. spiralis*. Experimentally, guinea-pigs and rabbits are readily infected by feeding them with muscle containing the larval form. Dogs are infected with difficulty; cats more readily. In the hog the trichinae, like the cysticerci, cause few if any symptoms. An important point is that in the hog the capsule is not readily calcified, so that the parasites are not visible as in the human muscles.

The anatomical changes are chiefly in the voluntary muscles. The trichinae enter the primitive muscle bundles, which undergo granular degeneration with marked nuclear proliferation. There is a local myositis, and gradually about the parasite a cyst wall is formed. These changes, as well as the remarkable alterations in the blood, have been described by Brown. Cohnheim described a fatty degeneration of the liver and enlargement of the mesenteric glands. At the time of death, in the fourth or fifth week or later, the adult trichinae are still found in the intestines.

Infection.—Man is infected by eating the flesh of trichinous hogs. In Germany, where a systematic microscopic examination of all swine flesh is made, the proportion of trichinous hogs is about 1 in 1,852. Statistics are not available in England. In America inspections have been made since 1892. The percentage of animals found infected has ranged from 1.04 to 1.95. In 1883, with A. W. Clement, the senior author examined 1,000 hogs at the Montreal abattoir, and found only 4 infected.

The danger of infection depends entirely upon the mode of preparation of the flesh. Thorough cooking, so that all parts of the meat reach the boiling point, destroys the parasites; but in large joints the central portions are often not raised to this temperature. The frequency of the disease in different countries depends largely upon the habits of the people in the preparation of pork. In North Germany, where raw ham and *Wurst* are freely eaten, the greatest number of instances have occurred. In South Germany, France, and England cases are rare. In the United States H. U. Williams, of Buffalo, made a thorough study of the muscle from 505 unselected autopsies, and found 27 cases of trichiniasis, 5.3 per cent. The subjects had all died of causes other than trichiniasis. This important study shows how widespread is the disease, and that we frequently overlook the sporadic form. Salting and smoking the flesh are not always sufficient, and animals are readily infected when fed with portions of pickled or smoked meat as prepared in America. Carl Fraenkel, however, states that the experiments on this point have been negative, and that it is very doubtful if any cases of trichiniasis in Germany have been caused by American pork. Germany has yet to show a single case of trichiniasis due to pork of unquestioned American origin.

The disease occurs in groups or outbreaks in which from a dozen to several hundred individuals are attacked, and in sporadic cases which have been shown of late years to be not infrequent. In the epidemics a large number of persons are infected from one source; in the two famous outbreaks of Hedersleben and Emersleben 337 and 250 individuals were attacked. In the United States Stiles estimates that there have been more than 1,000 small outbreaks. The discovery in the wards at the Johns Hopkins Hospital by T. R. Brown of the

eosinophilia in the disease has led to the much more frequent detection of the sporadic cases, and this form of the disease is not at all uncommon in the United States.

Symptoms.—The ingestion of trichinous flesh is not necessarily followed by the disease. When a limited number are eaten only a few embryos pass to the muscles and may cause no symptoms. Well-characterized cases present a gastro-intestinal period and a period of general infection.

In the course of a few days after eating the infected meat there are signs of gastro-intestinal disturbance—pain in the abdomen, loss of appetite, vomiting, and sometimes diarrhoea. The preliminary symptoms, however, are by no means constant, and in some of the large epidemics cases have been observed in which they have been absent. In other instances the gastro-intestinal features have been marked from the outset, and the attack has resembled cholera nostras. Pain in different parts of the body, general debility, and weakness have been noted in some of the epidemics.

The invasion symptoms occur between the seventh and the tenth day, sometimes not until the end of the second week. Chills are not common. There is fever, except in very mild cases, rising to 102° or 104° F.; the fever is usually remittent or intermittent. The migration of the parasites into the muscles excites a more or less intense *myositis*, which is characterized by pain on pressure and movement, and by swelling and tension of the muscles, over which the skin may be oedematous. The limbs are placed in the positions in which the muscles are in least tension. The involvement of the muscles of mastication and of the larynx may cause difficulty in chewing and swallowing. In severe cases the involvement of the diaphragm and intercostal muscles may lead to intense dyspnoea, which sometimes proves fatal. Œdema, a feature of great importance, may be early in the face, particularly about the eyes. Later it occurs in the extremities when the swelling and stiffness of the muscles are at their height. Profuse sweats, tingling and itching of the skin, and in some instances urticaria, have been described. Kernig's sign is usually present and the leg reflexes may be absent. There may be various signs of central nervous system involvement.

A marked leucocytosis, which may reach above 30,000, is usually present. A special feature is the extraordinary increase in the number of eosinophilic cells, which may comprise more than 50 per cent. of all the leucocytes.

The general nutrition is much disturbed and the patient becomes emaciated and often anæmic, particularly in the protracted cases. The patients are usually conscious, except in cases of very intense infection, in which the toxæmia, dry tongue, and tremor give a picture suggesting typhoid fever. In addition to the dyspnoea present in the severer infections, there may be bronchitis, and in the fatal cases pneumonia or pleurisy. In some epidemics polyuria has been a common symptom. Albuminuria is frequent.

The intensity and duration of the symptoms depend entirely upon the grade of infection. In mild cases the duration is from ten to fourteen days. In the severe forms convalescence is not established for six or eight weeks, and it may be months before the patient recovers his strength. One patient in the Hedersleben epidemic was weak eight years after the attack. Of 72 fatal cases in this epidemic, the greatest mortality occurred in the fourth and fifth and sixth weeks; namely, 52 cases. Two died in the second week with severe

choleraic symptoms. The mortality has ranged in different outbreaks from 1 or 2 to 30 per cent. Among 456 cases reported in the United States there were 122 deaths.

The prognosis depends much upon the quantity of infected meat eaten and the number of trichinæ which mature in the intestines. In children the outlook is more favorable. Early diarrhœa and moderately intense gastro-intestinal symptoms are, as a rule, more favorable than constipation.

Diagnosis.—The disease should always be suspected when a large party among Germans is followed by cases of apparent typhoid fever. The parasites may be found in the remnants of the ham or sausages used on the occasion. The worms may be found in the stools or in the duodenal contents. The stools should be spread on a glass plate or black background and examined with a low-power lens, when the trichinæ are seen as small, glistening, silvery threads. In doubtful cases the diagnosis may be made by the removal of a piece of muscle. The disease may be mistaken for rheumatic fever, particularly as the pains are so severe on movement, but there is no arthritis. The great increase of the eosinophiles in the blood is a most suggestive point in diagnosis. The tenderness is in the muscles both on pressure and on movement. The intensity of the gastro-intestinal symptoms has led to the diagnosis of cholera. Many epidemics have been described as typhoid fever, which the severer cases, owing to the prolonged fever, sweats, delirium, dry tongue, and gastro-intestinal symptoms, somewhat resemble. The pains in the muscles, with tension and swelling, œdema, particularly about the eyes, and shortness of breath, are the most important diagnostic points.

Prophylaxis.—Man must be regarded as an accidental host and prophylaxis in the human must depend on the proper cooking of pork for which a temperature of 137° F. is sufficient. "In the last analysis the responsibility for trichiniasis lies in the kitchen" (Stiles). This is especially important for the various sausages which are cooked before being sold. In other words, all pork and pork products should be thoroughly cooked.

Treatment.—If it has been discovered within twenty-four or thirty-six hours or even later that persons have eaten infected pork, the indications are to thoroughly evacuate the gastro-intestinal canal. Calomel (gr. ii, 0.13 gm.) should be given at once and four hours after the second dose half an ounce of castor oil or magnesium sulphate should be given and repeated if necessary. An enema should be given unless the bowels move freely. Glycerine has been recommended in large doses, in order that by passing into the intestines it may by its hygroscopic properties destroy the worm. Male fern, santonin, and thymol have all been recommended in this stage. Turpentine may be tried in full doses. There is no doubt that diarrhœa in the first week or ten days of the infection is distinctly favorable. The indications in the stage of invasion are to relieve the pains, to secure sleep, and to support the patient's strength. There are no medicines which have any influence upon the embryos in their migration through the muscles. The use of arsphenamine has been advised but proof of its value is lacking.

3. UNCINARIASIS

This is one of the most important and widespread of all metazoan infections, also known as hookworm disease, ankylostomiasis, anæmia of miners, bricklayers, tunnel-workers; tropical and Egyptian chlorosis.

History.—For three centuries the disease, but not its nature, was recognized in the tropics under various names. Dubini, in 1838, first described the worms, and gave the name from the curved or bent appearance of the mouth. In 1853 and 1854 Bilharz and Griesinger recognized the relation of the parasites to the anæmia and dropsy. In South America in 1866 Wucherer called attention to the frequency of the disease in negro slaves. In the "seventies" and "eighties" of the last century the anæmia of brick-workers in Italy and of miners and tunnel diggers was shown to be due to this parasite. Occasional statements were made as to the occurrence of the disease in the United States, but it was not until the extensive investigations of Stiles in 1901, and later, that it was shown that the hookworm was widely prevalent, that it was responsible for an enormous amount of ill health and anæmia, and that it was directly connected with the old and long-ago described practice of dirt-eating. It was gradually realized how widespread the disease was in the southern states. Ashford and King studied the disease in Porto Rico, and carried out one of the most successful of modern sanitary campaigns. In 1898 Looss discovered the cardinal fact of the penetration of the skin by the larvæ, and of the route by which they reach the intestine. There are many publications on the disease and bulletins may be obtained from the U. S. Public Health Service and many State Boards of Health.

Distribution.—The parasite exists in many parts of the world, and there is scarcely a tropical country in which it does not prevail. The prevalence of infection varies in different localities and it is very widespread especially in the tropics. In Europe it is chiefly an affection of miners in Germany, Hungary, France, and Belgium. In England there was a small outbreak in Cornwall, but the disease has not extended. Stiles showed that more than 12 per cent. of cotton-mill employees in the Southern United States were infected, and the examination of recruits, college students, and school children in different parts of the country gave a percentage of infection of from 20 to 70 or even 80. Among 18,390 white troops examined, hookworm was found in 13.7 per cent. In the West Indies the Rockefeller Commission found 97,632 infected among 165,866 examined.

Parasites.—There are two chief forms, the *Ancylostoma duodenale*, the old world species, and the *Necator americanus*, the new world species. The *Ancylostoma* is a small cylindrical nematode, the male about 10 mm. and the female from 8 to 18 mm. in length. The mouth has chitinous plates, and is provided with two pairs of sharp, hook-shaped teeth, with which they pierce the mucosa of the bowel. The male has a prominent, umbrella-like caudal expansion. The new world worm has much the same characters, but it is more slender, the mouth globular, and the arrangement of the teeth quite different. The eggs are from 52 μ to 60 μ by about 34 μ in width in the European form, and from 64 μ to 76 μ by about 36 μ in breadth in the American form. They are very characteristic bodies in the fæces of infected indi-

viduals. When laid they are already in process of segmentation. Complete desiccation and direct sunlight, or much water in the fæces kills the eggs; but they are sometimes very resistant, and may survive freezing followed by a gentle thawing. The rapidity of development depends upon favoring conditions and temperature, and the larvæ after escaping from the eggs may live for months in the mud or water of the mines, and pass through a series of moults before they reach what is called the ripe stage. They then show a remarkable tenacity of life, and may live in water or slime for many months; and in this, which is the infective stage, they have a great tendency to wander.

Modes of Infection.—An extraordinary number of eggs are passed with each stool of a badly infected person; it has been estimated as many as four millions. They develop most readily in fæces mixed with sand or earth at a temperature of from 70° to 90°. The eggs are not infective; the larvæ become infective when about 4 or 5 days old. Infection takes place either by the mouth directly, which is rare, or by the skin. Looss showed experimentally that the larvæ entering the skin are carried by the veins to the heart, and thence to the lungs, in which they escape from the pulmonary vessels, pass up the bronchi and trachea, and so to the gullet, stomach and intestines. These remarkable observations of Looss have been abundantly confirmed. As C. A. Smith's work has shown, it takes about seven weeks before the ova appear in the stools, and in the process of infection there may be sore throat and fever. It would appear that the skin is the common channel of entrance, and usually shows signs of irritation—*ground itch*. Ashford and King give a history of ground-itch in more than 90 per cent. of their cases. Larvæ accidentally swallowed may pass through the stomach, and develop in the intestines.

Morbid Anatomy and Pathology.—The worms are chiefly in the jejunum; Sandwith found 1,353 out of 1,524 worms in the first six feet of the bowel. They are also occasionally found in the stomach. A variable number of worms are found attached to the mucosa. Very characteristic lesions are the ecchymoses and small erosions of the mucosa, in the centre of which may be a pale area, slightly raised, to which the worm is attached; it may be almost buried in the mucosa. There are usually more bites or holes than worms. Blood cysts occur in the sub-mucosa, in which, occasionally, worms are found (Whipple). The contents of the bowel are often blood-stained. In long-standing cases the mucosa may show many areas of pigmentation. Other lesions are those of chronic anæmia with fatty degeneration. Much discussion has taken place as to whether the worms live on blood or not. They are certainly built for blood-sucking, and, as Whipple states, when the mucosa is normal the worms feed chiefly on blood, when it is thickened and infiltrated they have to be content with the epithelium and mucosa. The loss of blood is largely direct, but it has been shown by Loeb and A. J. Smith that the head-glands of the worm secrete a substance which retards coagulation, probably a hæmolytic poison, the presence of which Whipple has demonstrated. Another feature of importance is the liability to infection through the bites; and the anæmia may in part, at any rate, be due to poisonous products absorbed through the bowel lesions.

Symptoms.—Hookworm disease presents a very variable picture, nor does the severity of the symptoms seem to depend always upon the number of

worms. There have been fatal cases in which only ten or twelve worms were found, while recovery has followed after more than 4,000 worms have been expelled (Dock). In infected districts, as in the southern states, the hookworm disease causes a widespread degeneration in the community, the children and young adults showing a pallor, under-development, and failure of nutrition. With the infection, too, are associated apathy and lack of energy, so that the common opinion in the South is that the hookworm is the cause of laziness. There is no question that, as Stiles and others have shown, the widespread infection is responsible for a great deal of ill health and physical incapacity, often without any actual illness. In more severe cases the anæmia is pronounced, the hæmoglobin being from 40 to 50 per cent.; the child is stunted and puberty is long delayed, and the patient may belong to the group of dirt-eaters. The retardation of growth is remarkable, and the individual may continue to grow until he is 25 or 26 years of age. In the severest type of all the anæmia is still more pronounced; the hæmoglobin below 25 or 20 per cent.; œdema occurs, the patient is bedridden, and death occurs from exhaustion, diarrhœa, or some intercurrent affection. The *anæmia* is of a secondary type, averaging from 50 to 60 per cent. of the corpuscles, with, as a rule, a low color index. Leucocytosis is not often present, and the differential count shows nothing unusual except the great increase in the eosinophiles, ranging from 15 to 26 or even 30 per cent. The eosinophilia bears no relation to the severity of the infection.

"*Ground-itch*," the local lesion through which the parasites enter, is most common on the feet and legs in children, or on the arms and hands in gardeners and miners. The most common region is between and beneath the toes. The eruption is vesicular at first; then pustules form with a sticky exudate, and sometimes with much swelling of the skin. The vesicles and pustules gradually dry, and in eight or ten days heal with exfoliation.

Other general features are the circulatory and respiratory features of anæmia. The digestive symptoms are remarkable. In the mild cases there are slight epigastric pain and discomfort; in the severer ones there are anorexia and remarkable perversions of appetite; the patients eat earth, paper, chalk, starch, hair and clay. The dirt-eaters of the southern states are subjects of hookworm disease. With the apathetic, listless expression there is dilatation of the pupils, and Stiles has remarked upon the "dull, blank, almost fish-like or cadaveric stare," which gives a characteristic appearance.

Diagnosis.—In tropical and sub-tropical regions slight anæmia and ill health should lead to the examination of the stools, from which a certain diagnosis may be made by finding the eggs. "The combination of anæmia with under-development, weakness, dilated heart, and the history of ground-itch is not likely to be confused with anything else" (Stiles). In badly infected regions a fairly accurate diagnosis may be made on inspection alone, and this may be confirmed by the examination of the fæces and by the rapid improvement after the administration of thymol. Two or three drams of fæces suffice. The eggs are characteristic structures, usually containing 4 or 8 segments, sometimes the complete embryo nearly ready to burst its shell. Various estimates have been made of the number of worms based on the number of eggs found. It is to be remembered that the eggs vary greatly in number,

and the stools may be negative one day and contain many a few days later. Grassi states that 150 eggs per centigram of *fæces* represent about 1,000 worms. The adult worms may be found in the stools after giving an anthelmintic. The eosinophilia is an important diagnostic aid, but is not invariably present. Boycott and Haldane found that 94 per cent. of infected persons had over 8 per cent. of eosinophiles.

Prophylaxis.—Destruction of the adult worms, removing conditions suitable to the growth of the embryos, and a campaign of sanitary education are the three essentials. The proper disposal of *fæces*, obtaining a pure water supply, and decreasing the chance of infection by wearing shoes and stockings are important points. The work of the Porto Rico commission shows what can be done in the tropics, even in the most unfavorable surroundings. More than 300,000 persons have received specific treatment for the disease since the commission began its work. That the mortality in the island fell from 42 per 1,000 in 1899-1900 to 20.9 in 1910 is in great part due to the devoted work of the medical staff and the nurses in dealing with hookworm cases.

The International Health Board of the Rockefeller Foundation introduced the intensive method, which is an attempt as nearly as possible to relieve and control hookworm disease within a given area by sanitary and therapeutic measures. A census of the population is taken, a microscopic examination made of the stools, all infected persons are treated, and the treatment continued until a cure has resulted. The people are educated both as to the method of cure and the dangers of soil pollution.

In mines care should be taken to prevent local conditions favoring the growth of the embryos. Oliver has found that cinder and slag are destructive of the larvæ. New workers should be examined and proved not to have the disease before being admitted.

Treatment.—It is not safe to conclude too soon that all the worms have been removed, as a latent period, during which eggs are not produced, may last for some weeks after treatment. Several drugs are useful; the liquids are more efficient if given by the duodenal tube. The bowels should be opened before treatment and liquid diet given the day before. A dose of saline, such as sodium sulphate, is given the night before. Thymol is given twice in the morning, two hours apart, and a dose of saline two hours after the second dose. The dose of thymol is graduated according to the age of the patient, seven grains (0.5 gm.) for children under five, and increasing the dose according to age and strength to sixty grains (4 gm.) for adults. Very few ill effects follow its use, but it sometimes is irritating to the bowels, and occasionally it is toxic. This treatment should be carried out on one day of each week until the patient is cured. No alcohol or oil should be given at the time of administration of thymol.

Oil of chenopodium (wormseed oil) is often efficient, given in doses of 15 drops in castor oil every two hours for two or three doses. Two hours later a full dose of castor oil is given. Carbon tetrachloride is given in doses of 2 minims (0.13 c. c.) per year of age in children and in doses of 45 minims (3 c. c.) to adults, followed in two hours by a saline. Alcohol should not be taken for some time before or after. The *anæmia* should receive the usual treatment.

4. FILARIASIS

For a full discussion of the zoölogical relations of this important group see Stiles' article in our "System of Medicine."

The important species are:

Loa loa.—This is the eye-worm of tropical West Africa which causes "Calabar swellings." It occurs in the peripheral circulation during the day. The adults move about in the subcutaneous tissues.

Filaria bancrofti (Cobbold, 1877).—This is the most important blood filaria. The embryos are found in the peripheral circulation only during sleep or at night. The mosquito is the intermediate host. The embryos measure 270 to 340 μ long by 7 to 11 μ broad; tail pointed. The adult male measures 83 mm. long by 0.407 mm. broad; the tail forms two turns of a spiral. The adult female measures 155 mm. long by 0.715 mm. broad; eggs 38 μ by 14 μ . This is the species to which hæmatochyluria and elephantiasis are attributed. It is common in Central America and parts of South America. There are many cases in the West Indies and it is especially prevalent in some of the Pacific islands.

The female produces an extraordinary number of embryos, which enter the blood current through the lymphatics. Each embryo is within its shell, which is elongated, scarcely perceptible, and in no way impedes the movements. They are about the ninetieth part of an inch in length and the diameter of a red blood corpuscle in thickness, so that they readily pass through the capillaries. They move with the greatest activity, and form very striking and readily recognized objects under the microscope. A remarkable feature is the periodicity in the occurrence of the embryos in the blood. In the daytime they are almost or entirely absent, whereas at night, in typical cases, they are present in large numbers. This does not occur in the Pacific islands, one reason given being that there a day-feeding stegomyia mosquito is the common intermediary. The night-feeding *Culex fatigans* is not the usual carrier in these islands as it is in Asia, Africa and America. If, however, as Stephen Mackenzie has shown, the patient, reversing his habits, sleeps during the day, the periodicity is reversed. Lynch suggests that the periodicity is largely dependent on the difficulty of passage through the peripheral capillaries during periodic tonicities. Lothrop and Pratt calculated the number of embryos per cubic centimetre of blood hourly during the night; it rose steadily from four o'clock in the afternoon till midnight, when 2,100 per c. c. were present, then fell, none being found at ten o'clock the following morning. The further development of the embryos is associated with the mosquito, which sucks the blood and in this way frees them from the body. They develop in the mosquito and reach the proboscis from which they pass to the human host. The filariæ may be present in the body without causing any symptoms. In the blood of animals filariæ are very common and rarely cause inconvenience. It is only when the adult worms or the ova block the lymph channels that definite symptoms occur. Manson suggests that it is the ova (prematurely discharged), which are considerably shorter and thicker than the full-grown embryos, which block the lymph channels.

The parasite is widely distributed, particularly in tropical and sub-tropical countries. The disease exists in the Southern United States.

The effects produced may be described under the following conditions :

HÆMATOCHYLURIA.—Without any external manifestations, and in many cases without special disturbance of health, the subject from time to time passes urine of an opaque white, milky appearance, or bloody, or a chylous fluid which on settling shows a slightly reddish clot. The condition indicates dilatation and rupture of dilated lymphatics in some part of the urinary tract and obstruction of the thoracic duct. In a case described by Stephen Mackenzie the renal and peritoneal lymph plexuses were enormously enlarged, extending from the diaphragm to the pelvis. The thoracic duct above the diaphragm was impervious. The urine may be normal in quantity or increased. The condition is usually intermittent, and the patient may pass normal urine for weeks or months at a time. Microscopically, the chylous urine contains minute molecular fat granules, and usually red blood cells in various amounts. The embryos were first discovered by Demarquay, at Paris (1863), and in the urine by Wucherer, at Bahia, in 1866. It is remarkable for how long the condition may persist without serious impairment of the health. A patient seen by Dawson had hæmatochyluria intermittently for eighteen years. The only inconvenience had been in the passage of blood-clots which collected in the bladder. Chyluria is not always due to filaria. There is a nonparasitic form.

2. **ELEPHANTIASIS** is common in all countries in which the filariæ prevail. The parasites are not always found in the blood. The condition is more common in the legs, one or both, beginning below the knee, but gradually involving the entire limb. Next in frequency is *lymph-scrotum* and other forms involving the genitalia. The *scrotal* tumor may reach an enormous size, and 40 to 50 pounds in weight. The onset may be painless and slow, or sudden with fever, rapid swelling and redness of the part. There may be a series of such attacks, each one leaving the part more swollen. The so-called “elephantoid fever” may occur in all forms of the infection.

Among other conditions are: *varicose groin glands* which lessen or disappear when the patient lies down and are easily mistaken for hernia; *orchitis* which may appear and subside rapidly; *hydrocele* often follows it; *filarial abscesses* which may be deeply seated and contain dead adult worms.

Sporadic Elephantiasis.—A non-parasitic type may be mentioned here, which is not very uncommon in temperate regions, characterized by a progressive enlargement of a limb or portion of the body, with a hyperplasia of the skin and subcutaneous tissues, due apparently to an obstructive inflammation of the lymph-vessels. It may arise spontaneously without any obvious cause, or follow an inflammation of the skin of the part, occasionally removal of the lymph-glands. The legs are most frequently involved, beginning usually in one leg, about the foot or ankle, and gradually extending until the whole leg is greatly enlarged. The skin is usually smooth, but it may be hard and indurated or warty and nodular. Most of the cases are in young women, in whom the affection has come on without any obvious cause and progressed slowly until the leg was greatly enlarged. In one case eight years elapsed before the other leg became involved, and in another case more than ten years passed with the disease still confined to one leg.

Diagnosis.—The filaria larva may be found in the blood, urine or chylous fluid. A negative finding does not exclude filarial infection. Adult worms may be found in lymph glands or in abscesses. Eosinophilia is present.

Treatment.—So far as known, no drug destroys the embryos in the blood with certainty. In infected districts protection of the infected and well from mosquitoes is essential. In cases of chyluria the patients should use a dry diet and avoid all excess of fat. The chyle may disappear quite rapidly from the urine under these measures, but it does not necessarily indicate that the case is cured. So long as clots and albumin are present the leak in the lymphoid varix is not healed, although the fat, not being supplied to the chyle, may not be present. A single tumblerful of milk will at once give ocular proof of the patency or otherwise of the rupture in the varix (Manson).

Elephantoid fever demands rest, liquid diet, free purgation and sedative applications to painful areas. In *elephantiasis* during periods with acute symptoms the patient should be at rest and the legs firmly bandaged. Good results are reported from the use of fibrolysin.

The surgical treatment of some cases is most successful, particularly in the removal of the adult filariæ from the enlarged lymph-glands, especially in the groin. Surgical measures may be advisable in elephantiasis.

5. DRACONTIASIS (*Guinea-worm Disease*)

Dracunculus medinensis is a widely spread parasite in parts of Africa, India and Brazil. In the United States instances occasionally occur. Jarvis reported a case in a post chaplain who had lived at Fortress Monroe, Va., for thirty years. Van Harlingen's patient, a man aged forty-seven, had never lived out of Philadelphia, so that the worm must be included among the parasites of the United States. A majority of the cases reported in American journals have been imported.

The female develops in the subcutaneous and intermuscular connective tissues and produces vesicles and abscesses. In the large majority of the cases the parasite is found in the leg. Of 181 cases, in 124 the worm was found in the feet, 33 times in the leg, and 11 times in the thigh. It is usually solitary, though there are cases on record in which six or more have been present. It is cylindrical in form, about 2 mm. in diameter, and from 50 to 80 cm. in length. The male has been found by Leiper in a monkey, a very small worm only 22 mm. in length.

In water the embryos develop in a cyclops—a small crustacean—and it seems likely that man is infected by drinking the water containing these developed larvæ. It is probable that both male and female are ingested; but the former dies and is discharged, while the latter after impregnation penetrates the intestine and attains its full development in the subcutaneous tissues, where it may remain quiescent for a long time and can be felt beneath the skin like a bundle of string. The worm contains an enormous number of living embryos, and to enable them to escape she travels slowly downward head first, and usually reaches the foot or ankle. The head then penetrates the skin and the epidermis, forms a little vesicle, which ruptures, and a small ulcer is left, at the bottom of which the head often protrudes. The distended uterus ruptures and the embryos are discharged in a whitish fluid. After getting rid of them the worm will spontaneously leave her host.

When the worm first appears it should not be disturbed, as after parturition it may leave spontaneously. When the worm begins to come out

a common procedure is to roll it round a portion of smooth wood and in this way prevent the retraction, and each day wind a little more until the entire worm is withdrawn. Special care must be taken to prevent tearing of the worm, as severe inflammation may follow this.

The parasite may be excised entire, or killed by injections of bichloride of mercury (1 to 1,000). Asafoetida in full doses is said to kill the worm.

6. OTHER NEMATODES

Filaria.—Among less important filarian worms parasitic in man the following may be mentioned: *Filaria volvulus* occurs on the West Coast of Africa. It causes masses in the axillæ which are easily removed. *F. immitis*—the common *F. sanguinis* of the dog—of which Bowlby described two cases in man. In one case with hæmaturia female worms were found in the portal vein, and the ova were present in the thickened bladder wall and in the ureters. *F. equina* has rarely infected man.

Trichocephaliasis.—*Trichuris trichiura* (whipworm) is not infrequently found in the cæcum and large intestine of man. It measures from 4 to 5 cm. in length, the male being somewhat shorter than the female. The worm is readily recognized by the remarkable difference between the anterior and posterior portions. The former, which forms at least three-fifths of the body, is extremely thin and hair-like in contrast to the thick hinder portion of the body, which in the female is conical and pointed, and in the male more obtuse and usually rolled like a spring. The eggs are oval, lemon-shaped, 0.05 mm. in length, and provided with a button-like projection.

The number of the worms is variable, as many as a thousand having been counted. It is a widely spread parasite. In parts of Europe it occurs in from 10 to 30 per cent. of all bodies, but in the United States it is not so common. In 285 West Indian workers at Panama Darling found 46 per cent. infected. It is possible, he thinks, that these parasites play a rôle in amebic dysentery, the lesions of which begin at the exact location of the points of their attachment. The whipworm rarely causes symptoms. French and Boycott found ova in 40 of 500 Guy's Hospital patients. They found no etiological relationship of the parasite to appendicitis. Several cases have been reported in which profound anæmia occurred with this parasite, usually with diarrhœa. Enormous numbers may be present without producing any symptoms. The *diagnosis* is readily made by the examination of the fæces, which contain the characteristic lemon-shaped, hard, dark-brown eggs. In *treatment*, thymol or oil of chenopodium may be used.

Diectophyme renale (*Eustrongylus gigas*).—This enormous nematode, the male of which measures about a foot in length and the female about three feet, occurs in many animals and has occasionally been found in man. It is usually found in the renal region and may entirely destroy the kidney.

Anguillula aceti.—The *Anguillula aceti*, or vinegar eel, is sometimes present in urine and has been found in the bladder. It may be mistaken for a filarial parasite.

Strongyloides stercoralis.—The parasite was discovered in 1876 by Normand, and was formerly described as *Anguillula intestinalis*. It is a common parasite in tropical diarrhœa, particularly in Cochin China, but has a wide

distribution in tropical and subtropical countries. It is found in the Southern United States. When in large numbers they cause diarrhœa, but Darling concludes that they are not the cause of severe diarrhœa, though they may produce moderate anæmia. The mother worm burrows in the mucous membrane and deposits ova. The parasite is found in the upper parts of the small intestines. They are met with occasionally in the temperate regions. Thymol, oil of chenopodium and sulphur are useful in treatment.

IV. PARASITIC ARACHNIDA AND TICKS

Pentastomes.—(1) *LINGUATULA RHINARIA* (*Pentastoma tænioides*) has a somewhat lancet-shaped body, the female being from 3 to 4 inches in length, the male about an inch in length. The adult worm infects the frontal sinuses and nostrils of the dog, more rarely of the horse. The larval form, known as *Linguatula serrata* (*Pentastomum denticulatum*), is seen in the internal organs, particularly the liver, but has also been found in the kidney. The adult worm has been found in the nostril of man, but is rare and seldom occasions any inconvenience. The larvæ are not uncommon, particularly in parts of Germany. The parasite is very rare. Flint refers to a Missouri case in which from 75 to 100 parasites were expectorated. The liver was enlarged and the parasites probably occupied this region.

(2) The *ARMILLIFER ARMILLATUS* (*Pentastomum constrictum*) has the length of half an inch, with twenty-three rings on the abdomen. It is found in the Congo district and in parts of Asia. The larvæ, found in cysts in the lungs and liver, cause disease as they wander. The adult form lives in the nasal cavities and lungs of pythons and other snakes and man is infected probably through the drinking water.

Arachnidism (*Spider poisoning*).—The bite of the spider, *Lactrodectus mactans*, causes a stinging sensation followed by pain. Later there are anxiety, sweating, dyspnœa, nausea, vomiting, retention of the urine, and sometimes delirium. Tremors, convulsions and paralysis have followed. The acute symptoms subside in a few hours but some days are required for complete recovery.

Demodex (*Acarus*) **folliculorum** (**var. hominis**).—A minute parasite, from 0.3 mm. to 0.4 mm. in length, which lives in the sebaceous follicles, particularly of the face. It is doubtful whether it produces any symptoms. Possibly when in large numbers they excite inflammation leading to acne.

Sarcoptes (*Acarus*) **scabiei** (*Itch Insect*).—This is the most important of the arachnid parasites. The male is 0.23 mm. in length and 0.19 mm. in breadth; the female is 0.45 mm. in length and 0.35 mm. in width. The female can be seen readily with the naked eye and has a pearly-white color. It is not so common in the United States and Canada as in Europe.

The insect lives in a small burrow, about 1 cm. in length, which it makes for itself in the epidermis. At the end of this burrow the female lives. The male is seldom found. The chief seat of the parasite is in the folds where the skin is most delicate, as in the web between the fingers and toes, the backs of the hands, the axilla, and the front of the abdomen. The head and face are rarely involved. The lesions which result from the presence

of the itch insect are very numerous and result largely from the irritation of scratching. The commonest is a papular and vesicular rash, or, in children, an ecthymatous eruption. The irritation and pustulation which follow the scratching may completely destroy the burrows, but in typical cases there is rarely doubt as to the diagnosis.

The *treatment* consists of warm baths with a thorough scrubbing and use of a soft soap, after which the skin should be anointed with sulphur ointment, which for children should be diluted. An ointment of naphthol (dram to the ounce) is very efficacious. The clothing should be sterilized.

Leptus autumnalis (*Harvest Bug*).—This reddish-colored parasite, about half a millimetre in size, is often found in large numbers in fields and in gardens. They attach themselves to animals and man with their sharp proboscides, and the hooklets of their legs produce a great deal of irritation. They are most frequently found on the legs. They are readily destroyed by sulphur ointment or corrosive-sublimate lotions.

Ixodiasis (*Tick-fever*).—In South Africa, particularly in the western provinces of the Uganda Protectorate, the western districts of German East Africa and the eastern regions of the Congo Free State, there is a disease known by this name, believed to be transmitted by a tick—the *Ornithodoros* or *Argas moubata*. The ticks live in old houses, and their habits are very much like those of the common bed-bug. This tick transmits the *Spirochaeta duttoni*, the cause of the African form of relapsing fever.

The *Dermacentor andersoni* is present in the northwestern states from California to Montana. The bites may cause severe lymphangitis. It is the medium of transmission of the Rocky Mountain spotted fever.

Otobius megnini (spinose ear tick) is widely spread over the western and southwestern states. The tick enters the ear in the larval stage and buries itself between folds of skin. Animals are frequently infected. The local symptoms are marked. Chloroform vapor followed by syringing or the introduction of oil is effective in removal. Several other varieties of ticks are occasionally found on man—the *Ixodes ricinus* and the *Dermacentor americanus*, which are met with in horses and oxen.

Tick Paralysis.—In connection with the bites of ticks of the genus *Ixodes* and the genus *Dermacentor* a flaccid paralysis of the legs has been described, particularly in British Columbia, Wyoming, Montana, and possibly in Australia. Children are usually affected, and, curiously enough, if the tick is found and removed promptly, the child gets well within twenty-four hours, but if not, the paralysis may spread to the arms, stupor may come on, and the child may die of a widespread paralysis. In adults sometimes there are pain, an erythematous rash, and vertigo. It appears to be a toxic effect of the parasite and not an infection.

V. PARASITIC INSECTS

Pediculi (*Phthiriasis; Pediculosis*).—There are three varieties:

PEDICULUS HUMANUS (*Head Louse*).—The male is from 1 to 1.5 mm. in length and the female nearly 2 mm. The color varies somewhat with the different races of men. It is light gray with a black margin in the European, and

very much darker in the negro and Chinese. They are oviparous, and the female lays about sixty eggs, which mature in a week. The ova are attached to the hairs, and are known popularly as nits. The symptoms are irritation and itching of the scalp. When numerous, the insects may excite an eczema or a pustular dermatitis, which causes crusts and scabs, particularly at the back of the head. In extreme cases the hair becomes tangled in these crusts and matted together, forming a firm mass which is known as *plica polonica*, as it was not infrequent among the Jewish inhabitants of Poland.

PEDICULUS CORPORIS (*vestimentorum*).—This is considerably larger than the head louse. It lives on the clothing, and in sucking the blood causes minute hæmorrhagic specks, which are very common about the neck, back, and abdomen. The irritation of the bites may cause urticaria, and the scratching is usually in linear lines. In long-standing cases, particularly in old dissipated characters, the skin becomes rough and greatly pigmented, a condition which has been termed the vagabond's disease—*morbus errorum*—which may be mistaken for the bronzing of Addison's disease. The pigmentation may be extreme and extend to the face and buccal mucosa.

PHTHIRIUS PUBIS (*crab louse*) differs somewhat from the other forms, and is found in the parts of the body covered with short hairs, as the pubes; more rarely the axilla and eyebrows.

The *taches bleuâtres*, *maculæ ceruleæ*, or *peliomata*, excited by the irritation of pediculi, are peculiar subcuticular bluish or slate-colored spots from 5 to 10 mm. in diameter seen about the abdomen and thighs, particularly in febrile cases. The spots are more marked on white thin skins. They are stains caused by a pigment in the secretion of the salivary glands of the louse.

TREATMENT.—For the *Pediculus humanus*, when the condition is very bad, the hair should be cut short, as it is very difficult to destroy all the nits. Repeated saturations of the hair in coal-oil or in turpentine are usually efficacious, or with lotions of carbolic acid, 1 to 50. The application of a mixture of equal parts of xylene, alcohol and ether is useful. Scrupulous cleanliness and care are sufficient to prevent recurrence. In the case of the *Pediculus corporis*, the clothing should be placed for hours in a disinfecting oven. To allay the itching a warm bath containing 4 or 5 ounces of bicarbonate of soda is useful. For the *Phthirius pubis* white precipitate or ordinary mercurial ointment should be used, and the parts should be thoroughly washed two or three times a day with soft soap and water.

Cimex lectularius (*Common Bed-bugs*).—The tropical and sub-tropical variety is *Cimex rotundalius* (W. S. Patton). It lives in the crevices of the bedstead and in the cracks in the floor and in the walls. It is nocturnal in its habits. The peculiar odor of the insect is caused by the secretion of a special gland. The parasite possesses a long proboscis, with which it sucks the blood. Individuals differ remarkably in the reaction to the bite of this insect; some are not disturbed in the slightest by them, in others the irritation causes hyperæmia and often intense urticaria. Fumigation with sulphur or scouring with corrosive-sublimated solution or kerosene destroys them. Iron bedsteads should be used.

Pulex irritans (*Common Flea*).—The male is from 2 to 2.5 mm. in length, the female from 3 to 4 mm. The flea is a transient parasite on man. The bite causes a circular red spot of hyperæmia in the centre of which is a

little speck where the boring apparatus has entered. The amount of irritation caused by the bite is variable. Many persons suffer intensely and a diffuse erythema or an urticaria develops; others suffer no inconvenience.

The *Tunga penetrans* (sand-flea, jigger) is found in tropical countries, particularly in the West Indies and South America. It is much smaller than the common flea, and not only penetrates the skin, but burrows and produces an inflammation with pustular or vesicular swelling. It most frequently attacks the feet. It is readily removed with a needle. Where they exist in large numbers the essential oils are used on the feet as a preventive.

VI. PARASITIC FLIES

(*Myiasis, Myiosis*)

The accidental invasion of the body cavities and of the skin by the larvæ of the diptera is known as myiasis.

The larvæ of the *Comptosia macellaria*, the so-called screw-worm, have been found in the nose, in wounds, and in the vagina after delivery. They can be removed readily with forceps; if there is any difficulty, thorough cleansing and the application of an antiseptic solution are sufficient to kill them. The ova of the blue-bottle fly may be deposited in the nostrils, ears, or conjunctiva. This rarely takes place unless these regions are the seat of disease. In the nose and in the ear the larvæ may cause serious inflammation. Even the urethra has not been spared in these dipterous invasions.

Gastro-intestinal myiasis may result from the swallowing of the larvæ of the common house-fly or of other species. There are many cases on record in which the larvæ of the *Musca domestica* have been discharged by vomiting. Instances in which dipterous larvæ have been passed in the fæces are less common. Finlayson, of Glasgow, reported an interesting case in a physician, who, after protracted constipation and pain in the back and sides, passed large numbers of the larvæ of the flower-fly—*Anthomyia canicularis*. Among other forms of larvæ or gentles, as they are sometimes called, which have been found in the fæces are those of the common house-fly, the blue-bottle fly, and the *Techomyza fusca*. The larvæ of other insects are extremely rare. It is stated that the caterpillar of the taby moth has been found in the fæces. A specimen of the *Homalomyia scalaris*, one of the privy flies, was sent by Dr. Hartin, of Kaslo City, B. C., the larvæ of which were passed in large numbers in the stools of a man, a native of Louisiana. They were present in the stools from May 1 to July 15, 1897. There are cases in which the larvæ have been passed for years.

Although no grave results necessarily follow the invasion by these larvæ, yet they may be the cause of serious intestinal ulceration manifesting itself by a dysenteric disease with fatal result. Cockayne states that there are four deaths on record. In treatment, the bowels should be cleared by castor oil.

Cutaneous Myiasis.—The most common form is that in which an external wound becomes "living," as it is called due to the larvæ of the blue-bottle or the common flesh-fly. The skin may also be infected by the larvæ of the *Musca vomitoria*, but more commonly by the bot-flies of the ox and sheep which occa-

sionally attack man. This is rare in temperate climates. Matas described a case in which œstrus larvæ were found in the gluteal region. In parts of Central America the eggs of another bot-fly, the *Dermatobia*, may be deposited in the skin and produce a swelling very like the ordinary boil.

Dermamyiasis linearis migrans œstrosa is a remarkable cutaneous condition, observed particularly in Russia and occasionally in other countries, in which the larva of *Gastrophilus equi* (Samson), the horse bot-fly, makes a slightly raised pale red "line" which travels over the body surface sometimes with great rapidity. It has been referred to as Larva migrans and as Creeping Eruption. (See Hamburger, Journal of Cutaneous Diseases, 1904.)

In Africa the larvæ of the Caylor fly are not uncommonly found beneath the skin in little boils. In the Congo region Dutton, Todd, and Christy found a troublesome blood-sucking dipterous larva, known as the floor maggot, the fly of which is the *Anchmeromyia luteola*.

Caterpillar Rash.—In some districts in Europe the hairs of the procession caterpillar, particularly of the species *Cnethocampa*, cause an intense urticaria, the so-called *U. epidemica*. There are districts in Switzerland rendered uninhabitable in consequence of the skin rashes caused by the caterpillars. In New England and other parts of the United States the caterpillar of the brown-tailed moth has caused much discomfort. The hairs are widely distributed, and the barbs readily work into the skin. Whole families have been affected by an intense eruption which has been mistaken for that of small-pox. In England, Thresh called attention to the frequency of these caterpillar rashes due to the yellow-tailed moth, *Porthesia similis*.

Harvest Rash (*Erythema Autumnale*).—In parts of England during the autumn many people are attacked by the harvest bug or harvesters, which may cause an obstinate and distressing malady. Usually attributed to the harvest spider, it is in reality caused by a mite, parasitic upon it, the hexapod larva of the silky trombidian. It is so small as to be scarcely visible and is brick-red in color. They chiefly attack persons with delicate skins, on the ankles and legs, but also attack the arms and neck. The mite attaches itself to the skin by its claws, sucks the blood, and the swollen red abdomen may sometimes be seen as a bright-red dot. A papulo-vesicular, sometimes a pustular, eruption with an intolerable itching is caused by it. So intense may the eruption be, with perhaps an entire family attacked, that suspicion of poisoning is aroused. The parasite is readily killed by benzine.

E. INFECTIOUS DISEASES OF DOUBTFUL OR UNKNOWN ETIOLOGY

I. SMALL-POX (Variola)

Definition.—An acute infectious disease characterized by a cutaneous eruption which passes through the stages of papule, vesicle, pustule, and crust. A secondary streptococcus infection is an important feature.

History.—The existence of the disease in ancient Egypt is suggested by the eruption on the skin of a mummy of the 20th dynasty—1,200 to 1,100

B. C. (Rüffer and Ferguson). The disease existed in China many centuries before Christ. The *pesta magna* described by Galen (of which Marcus Aurelius died) is believed to have been small-pox. In the sixth century it prevailed, and subsequently, at the time of the Crusades, became widespread. It was brought to America by the Spaniards early in the sixteenth century. The first accurate account was given by Rhazes, an Arabian physician who lived in the ninth century, and whose admirable description is available in Greenhill's translation for the Sydenham Society. In the seventeenth century the illustrious Sydenham differentiated measles from small-pox. Special events in the history of the disease are the introduction of inoculation into Europe, by Lady Mary Wortley Montagu, in 1718, and the discovery of vaccination by Jenner, in 1796.

Etiology.—Small-pox is one of the most virulent of infectious diseases, and persons exposed, if unprotected by vaccination, are almost invariably attacked. Instances of natural immunity are rare. It is said that Diemerbroeck, a celebrated Utrecht professor in the seventeenth century, was not only himself exempt, but likewise many members of his family. An attack may not protect for life. There are undoubted cases of a second, reputed instances, indeed, of a third attack. Louis XV of France died of a second attack of small-pox.

AGE.—Small-pox is common at all ages, but is particularly fatal to young children. Of 3,164 deaths in the Montreal epidemic of 1885-'86, 2,717 were of children under ten years of age. The *fetus in utero* may be attacked, but only if the mother is the subject of the disease. The child may be born with the rash out or with the scars. In the case of twins, only one may be attacked; Kaltenbach records an instance of triplets, only two of which were affected (Comby). Children born in a small-pox hospital, if vaccinated immediately, may escape the disease; usually, however, they die early.

SEX.—Males and females are equally affected.

RACE.—Among aboriginal races small-pox is terribly fatal. When the disease was first introduced into America the Mexicans died by thousands, and the North American Indians have also been frequently decimated by this plague. It is stated that the negro is especially susceptible, and the mortality is greater—about 42 per cent. in the black, against 29 per cent. in the white (W. M. Welch).

It is claimed that isolation hospitals increase the incidence of the disease in a locality. J. Glaister, who considered the question very carefully, concludes that as a centre of traffic such an institution, through the channels of human intercourse, naturally favors the spread of the disease locally, but decides against its aerial conveyance, in spite of the strong evidence.

The disease smoulders here and there and when conditions are favorable becomes epidemic. This was well illustrated by the Montreal outbreak of 1885. For several years there had been no small-pox in the city, and a large unprotected population grew up among the French-Canadians, many of whom were opposed to vaccination. On February 28 a Pullman-car conductor, who had traveled from Chicago, was admitted into the Hôtel-Dieu, the civic small-pox hospital being closed at the time. Isolation was not carried out, and on the 1st of April a servant in the hospital died of small-pox. Following her decease, the authorities of the hospital dismissed all patients presenting no

symptoms who could go home. The disease spread like fire in dry grass, and in nine months 3,164 persons died in the city of small-pox.

VARIATIONS IN VIRULENCE.—Sydenham states that “small-pox also has its peculiar kinds, which take one form during one series of years, and another during another”; and not only does what he called the epidemic constitution vary greatly, but one sometimes sees the most extraordinary variations in the intensity of the disease in members of a family all exposed to the same infection. A striking illustration of this variability has been given in recent epidemics, which have been of so mild a character that in many localities it has been mistaken for chicken-pox. Very often a correct diagnosis is not reached until a fatal case has occurred. Even in unvaccinated children the disease has been exceedingly mild. In 1922, in the north of England among 821 cases there were 3 deaths and in London 74 cases with 24 deaths. This is an old story in the history of the disease. John Mason Good, in commenting on this very point, refers to the great variability in the epidemics, and states that he himself as a child of six (1770) passed through small-pox with “scarcely any disturbance and not more than twenty scattered pustules”!

Anomalous Forms.—In Africa, Australia, Brazil and the West Indies, an infection occurs known as alastrim, amaas or varioloid varicella, which is regarded as a mild form of small-pox. It attacks adults especially; the lesions are superficial and may appear in crops; the course is short and the mortality slight.

Recent Prevalence.—In the United States in 1925 there were 709 deaths in the registration area. The mild type of the disease continues, but in places there have been virulent outbreaks. In England and Wales there were 53 deaths from the disease in 1928. In California in 1916 there were 248 cases: in 1917, 329; in 1918, 1,100; in 1919, 2,053; and in 1920, 4,486 cases. Of 4,226 of the 1920 cases in which a vaccination history was obtained, 1 per cent. had been vaccinated in the preceding five years, 7 per cent. had been vaccinated over five years before, and 92 per cent. had never been vaccinated.

NATURE OF INFECTION.—Protozoön-like bodies were described in the skin lesions by Guarneri—*Cytoryctes variolæ*. Councilman and his colleagues describe a protozoön with a double cycle and cytoplasmic stage with small structureless bodies in the lower layer of the epithelial cells. Infection occurs probably by the nasal secretion and sputum. The dried scales are also an important element, and as a dust-like powder are distributed in the room during convalescence, becoming attached to clothing and articles of furniture. The disease is probably infectious from a very early stage, though it has not been determined whether the contagion is active before the eruption develops. The agent is of unusual tenacity and clings to infected localities. It is conveyed by persons who have been in contact with the sick and by fomites. During epidemics it is no doubt widely spread in street-cars and public conveyances. An unprotected person may contract a very virulent form of the disease from a patient with a mild attack. The virus is filterable; its nature is unknown.

Morbid Anatomy.—The cutaneous lesions are in the deeper epidermal layers. The pustules may be seen on the tongue, the buccal mucosa and the palate; sometimes also in the pharynx. In some cases the lesions are present in the œsophagus and even in the stomach. Swelling of the Peyer's follicles is not uncommon; the pustules have been seen in the rectum.

In the larynx the eruption may be associated with a fibrinous exudate and sometimes with oedema. Occasionally the inflammation penetrates deeply and involves the cartilages. In the trachea and bronchi there may be ulcerative erosions, but true pocks, such as are seen on the skin do not occur.

The heart occasionally shows myocardial changes; endocarditis and pericarditis are uncommon. French writers have described an endarteritis of the coronary vessels. The spleen is markedly enlarged. Apart from the cloudy swelling and areas of coagulation-necrosis, lesions of the kidneys are not common. Nephritis may occur.

In the hæmorrhagic form extravasations are found on the serous and mucous surfaces, in the parenchyma of organs, in the connective tissues, about the nerve-sheaths and in the muscles. In one instance the entire retro-peritoneal tissue was infiltrated with a large coagulum, and there were also extensive extravasations in the course of the thoracic aorta. Hæmorrhages in the bone-marrow have been described. The spleen is firm and hard in hæmorrhagic small-pox. In these rapidly fatal forms the liver has been described as fatty, but in 5 of 7 cases it was of normal size, dense, and firm.

Symptoms.—Different forms of small-pox are described, but they only represent various degrees of severity.

(a) ORDINARY SMALL-POX or VARIOLA VERA.—The period of *incubation* is from nine to fifteen days, usually twelve. The senior author saw it as early as the eighth day after exposure, and there are authenticated instances in which it was prolonged to twenty days. It is unusual for patients to complain of any symptoms.

CHART IX.—TRUE SMALL-POX (Strümpell).

Invasion.—In adults a chill and in children a convulsion are common initial symptoms. There may be repeated chills within the first twenty-four hours. Intense frontal headache, severe lumbar pains, and vomiting are very constant features. The pains in the back and in the limbs are more severe in the initial stage of this than of any other eruptive fever, and their combination with headache and vomiting is so suggestive that precautionary measures may often be taken several days before the eruption appears. The temperature rises quickly, and may on the first day be 103° or 104°. The pulse is rapid and full, not often dicrotic. In severe cases there may be marked

delirium, particularly if the fever is high. The patient is restless and distressed, the face flushed, and the eyes bright and clear. The skin is usually dry, though occasionally there are profuse sweats. One cannot judge from the initial symptoms whether a case is likely to be discrete or confluent, as convulsions, severe headache, and high fever may precede a mild attack.

Initial Rashes.—Two forms can be distinguished: the diffuse, scarlatinal, and the macular or measly form; either of which may be associated with petechiæ and occupy a variable extent of surface. In some instances they are general, but as a rule are limited either to the lower abdominal areas, to the inner surfaces of the thighs, to the lateral thoracic region, or to the axillæ. Occasionally they are found over the extensor surfaces, particularly in the neighborhood of the knees and elbows. These rashes, usually purpuric, are often associated with an erythematous or erysipelatous blush. The scarlatinal rash may come out as early as the second day, and be as diffuse and vivid as in true scarlet fever. The measly rash may also be diffuse and resemble closely that of measles. Urticaria is seen only occasionally. The initial rashes are more abundant in some epidemics than in others and occur in from 10 to 15 per cent. of cases.

Eruption.—(1) In the *discrete form*, usually on the third or fourth day, *macules* appear on the forehead, preceded sometimes by an erythematous flush, and on the anterior surfaces of the wrists. Within the first twenty-four hours from their appearance they occur on other parts of the face and on the extremities, and a few are seen on the trunk. The spots are from 2-3 millimetres in diameter, of a bright red color, and disappear completely on pressure. On the second day of the eruption the macular eruption becomes *papular*. As the rash comes out the temperature falls, the general symptoms subside, and the patient feels comfortable. On the third day of the eruption the papules change into vesicles with clear summits. Each one is elevated, circular, and presents a little depression or umbilication in the centre. They are divided into compartments and do not collapse if a single opening is made. They are *in the skin* rather than *on the surface*. About the fifth day of the eruption the vesicles change into pustules, the umbilication disappears, the flat top assumes a globular form and becomes grayish-yellow in color, owing to the contained pus. There is an areola of injection about the pustules and the skin between them is swollen. This maturation first takes place on the face, and follows the order of the appearance of the eruption. The temperature now rises—*secondary fever*—and the general symptoms return. The swelling about the pustules is attended with a good deal of tension and pain in the face; the eyelids become swollen and closed. In the discrete form the temperature of maturation does not usually remain high for more than twenty-four hours, so that on the tenth or eleventh day of the disease the fever disappears and the stage of convalescence begins. The pustules rapidly dry, first on the face and then on the other parts, and by the fourteenth or fifteenth day desquamation may be far advanced on the face. The distribution of the rash is often most characteristic. The abdomen, groins, axillæ and the legs are least affected. The rash is often copious on the upper part of the back, scanty on the lower. Vesicles in the mouth, pharynx, and larynx cause soreness and swelling in these parts, with loss of voice and the formation of shallow ulcers. Whether pitting takes place depends a good deal upon the severity of the dis-

ease. In a majority of cases Sydenham's statement holds good, that "it is very rarely the case that the distinct small-pox leaves its mark." The odor of a small-pox patient is very distinctive even in the early stages, and has been a help in the diagnosis of a doubtful case.

(2) *The Confluent Form*.—With the same initial symptoms, though usually of greater severity, the rash appears on the third or fourth day. The more the eruption shows itself before the fourth day the more sure it is to become confluent (Sydenham). The papules at first may be isolated, and it is only later in the stage of maturation that the eruption is confluent. But in severer cases the skin is swollen and hyperæmic and the papules are very close together. On the feet and hands, too, the papules are thickly set; more scattered on the limbs; and quite discrete on the trunk. With the appearance of the eruption the symptoms subside and the fever remits, but not to the same extent as in the discrete form. Occasionally the temperature falls to normal and the patient may be comfortable. Then, usually on the eighth day of the disease, the fever again rises, the vesicles change to pustules, the hyperæmia becomes intense, the swelling of the face and hands increases, and by the tenth day the pustules have fully matured, many have coalesced, and the entire skin of the head and extremities is a superficial abscess. The fever rises to 103° or 105° , the pulse is from 110 to 120, and there is often delirium. Salivation in adults and diarrhœa in children are common symptoms of this stage. There is usually much thirst. The eruption may be present in the mouth, and usually the pharynx and larynx are involved and the voice is husky. Great swelling of the cervical lymphatic glands occurs. At this stage the patient presents a terrible picture, unequaled in any other disease and one which fully justifies the horror and fright with which small-pox is associated in the public mind. Even when the rash is confluent on the face, hands, and feet, the pustules remain discrete on the trunk. The danger, as pointed out by Sydenham, is in proportion to the number upon the face. "If upon the face they are as thick as sand, it is no advantage to have them few and far between on the rest of the body." In fatal cases by the tenth or eleventh day the pulse gets feebler and more rapid, the delirium is marked, there is subsultus, sometimes diarrhœa, and with these symptoms the patient dies. In other instances between the eighth and eleventh day hæmorrhagic features occur. When recovery takes place, the patient enters on the eleventh or twelfth day the period of desiccation.

Desiccation.—The pustules break and the pus exudes or they dry and form crusts. Throughout the third week the desiccation proceeds and in cases of moderate severity the secondary fever subsides; but in others it may persist until the fourth week. The crusts in confluent small-pox adhere for a long time and the process of scarring may take three or four weeks. On the face they fall off singly, but the tough epidermis of the hands and feet may be shed entire.

Leucocytes.—In variola vera there is a marked leucocytosis, 12-16 thousand, about the eighth day, then a slight decline and a rise again about the twelfth or fourteenth day, sometimes to 18,000 or 20,000. There is an increase in the mononuclear elements, which may be the only marked feature of the mild cases (Magrath, Brinckerhoff, and Bancroft).

(b) *HÆMORRHAGIC SMALL-POX* occurs in two forms. In one, the petechial

or black small-pox—*purpura variolosa*—the special features appear early and death follows in from two to six days. In the other form the case progresses as one of ordinary variola, and in the vesicular or pustular stage hæmorrhages take place into the pocks or from the mucous membranes—*variola hæmorrhagica pustulosa*.

Purpura variolosa is more common in some epidemics than in others. It is less frequent in children than in adults and young and vigorous persons seem more liable to it. Men are more frequently affected than women; thus in one series there were 21 males and only 6 females. The influence of vaccination is shown in the fact that of the cases 14 were unvaccinated, while not one of the 13 who had scars had been revaccinated. The illness starts with the usual symptoms, but with more intense constitutional disturbance. On the second or the third day there is a diffuse hyperæmic rash, particularly in the groins, with small punctiform hæmorrhages. The rash extends, becomes more distinctly hæmorrhagic, and the spots increase in size. Ecchymoses appear on the conjunctivæ, and as early as the third day there may be hæmorrhages from the mucous membranes. Death may take place before the papules appear. In this truly terrible affection the patient may present a frightful appearance. The skin may have a uniformly purplish hue and the unfortunate victim may even look plum-colored. The face is swollen and large conjunctival hæmorrhages with the deeply sunken corneæ give a ghastly appearance. The mind may remain clear to the end. Death occurs from the third to the sixth day; in thirteen of the series it took place between these dates. The earliest death was on the third day and there were no traces of papules. Hæmaturia is perhaps most common, next hæmatemesis, and melæna was noticed in a third of the cases. The pulse is rapid and often hard and small. The respirations are greatly increased in frequency and out of all proportion to the intensity of the fever.

In *variola pustulosa hæmorrhagica* the disease progresses as a severe case, and the hæmorrhages do not occur until the vesicular or pustular stage. The first indication is hæmorrhage into the areolæ of the pocks, and later the matured pustules fill with blood. The earlier the hæmorrhage the greater is the danger. Bleeding from the mucous membranes is common and the great majority prove fatal, usually on the seventh, eighth, or ninth day, but a few recover. In patients with the discrete form, if allowed to get up early, hæmorrhage may take place into the pocks on the legs.

(c) VARIOLOID.—This term is applied to the modified form in persons who have been vaccinated. It may set in with abruptness and severity, the temperature reaching 103°. More commonly it is in every respect milder in its initial symptoms, though the headache and backache may be very distressing. The papules appear on the third or fourth day. They are few in number and may be confined to the face and hands. The fever drops at once and the patient feels perfectly comfortable. The maturation of the pocks takes place rapidly, and there is no secondary fever. There is rarely any scarring. As a rule, when small-pox attacks a person who has been vaccinated within five or six years the disease is mild, but it may prove severe, even fatal.

Abortive Types.—Recent epidemics have been characterized by the large number of mild cases. Even in unvaccinated children only a few pustules

may appear, and the disease is over in a few days. Even with a thickly set eruption the vesicles, instead of filling, dry and abort, forming the so-called horn-, crystalline-, or wart-pox. *Variola sine eruptione* is described. Bancroft observed twelve cases in a Boston outbreak, all among physicians and attendants. The symptoms are headache, pain in the back, fever, and vomiting. The pocks may be very scanty and easily overlooked, even in unvaccinated persons. One of Bancroft's cases was of special interest—a pregnant woman who had slight symptoms after exposure, but no rash. Her child showed a typical eruption when two days old.

Complications.—Considering the severity of many of the cases and the character of the disease, associated with multiple foci of suppuration, the complications in small-pox are remarkably few.

Laryngitis is serious in three ways: it may produce a fatal œdema of the glottis; it is liable to extend and involve the cartilages, producing necrosis; and by diminishing the sensibility of the larynx it may allow irritating particles to reach the lower air-passages, where they excite bronchitis or bronchopneumonia. *Broncho-pneumonia* is almost invariably present in fatal cases. *Lobar pneumonia* is rare. *Pleurisy* is common in some epidemics.

Cardiac complications are rare. At the height of the fever a systolic murmur at the apex is not uncommon; but endocarditis, either simple or malignant, is rare and pericarditis is uncommon. Myocarditis seems to be more frequent, and may be associated with endarteritis of the coronary vessels.

Of complications in the *digestive* system, parotitis is rare. In severe cases there is extensive pseudo-diphtheritic angina. Vomiting, so marked in the early stage, is rarely persistent. Diarrhœa is not uncommon, particularly in children. *Albuminuria* is frequent, but true *nephritis* is rare. Inflammation of the testes and ovaries may occur.

Among the serious complications are those pertaining to the *nervous system*. In children convulsions are common. In adults the delirium of the early stage may persist and become violent, and finally subside into a fatal coma. Post-febrile insanity is occasionally met with during convalescence, and very rarely epilepsy. Many of the old writers spoke of paraplegia with the intense backache of the early stage, but it is probably associated with the severe lumbar and crural pains and is not a true paraplegia. It must be distinguished from the form occurring in convalescence, which may be due to peripheral neuritis or diffuse myelitis (Westphal). The neuritis may involve the pharynx alone, or be multiple. Of this nature, in all probability, is the so-called pseudo-tabes, or *ataxie variolique*. Hemiplegia and aphasia have occurred in a few instances, the result of encephalitis.

Among the most constant and troublesome complications are those involving the *skin*. During convalescence boils are very frequent and may be severe. Acne and erythma are also met with. Alopecia may follow. Local gangrene in various parts may occur. A remarkable secondary eruption (recurrent small-pox) occasionally occurs after desquamation.

Arthritis may occur, usually in the period of desquamation, and may pass on to suppuration. Osteomyelitis is sometimes met with.

SPECIAL SENSES.—The eye affections are not now so frequent, owing to the care which is given to keeping the conjunctivæ clean. A catarrhal and

purulent conjunctivitis is common in severe cases. The secretions cause adhesions of the eyelids, and unless great care is taken a diffuse keratitis is excited, which may go on to ulceration and perforation. Iritis is not very uncommon. Otitis media may result from an extension of the disease through the Eustachian tubes.

Prognosis.—In unprotected persons small-pox is a very fatal disease, the death-rate ranging from 25 to 35 per cent. In the recent mild epidemics the mortality has been very slight, often less than 1 per cent. At the Municipal Hospital, Philadelphia, of 2,831 cases of variola, 1,534—i. e., 54.18 per cent.—died, while of 2,169 cases of varioloid only 28—i. e., 1.29 per cent.—died (W. M. Welch). Purpura variolosa is invariably fatal, and a majority of those with the severer confluent forms die. The intemperate and debilitated succumb more readily. As Sydenham observed, the danger is directly proportionate to the intensity of the disease on the face and hands. “When the fever increases after the appearance of the pustules, it is a bad sign; but if it is lessened on their appearance, that is a good sign” (Rhazes). Very high fever, delirium and subsultus are symptoms of ill omen. The disease is particularly fatal in pregnant women and abortion usually takes place but is not inevitable. Severe cases may recover after miscarriage. Very severe pharyngitis, laryngitis and broncho-pneumonia are serious complications.

Death results in the early stage from the action of the disease upon the nervous system. In the later stages it usually occurs about the eleventh or twelfth day, at the height of the eruption.

Diagnosis.—During an epidemic the initial chill, the headache and back ache, and the vomiting at once put the physician on his guard.

Certain general points may be mentioned. The nature of any prevailing epidemic, the possibility of exposure, previous vaccination and an exact history of the onset are important. The patient should be properly stripped and examined in good daylight, with careful inspection of the mouth and pharynx. The student should remember that, in the diagnosis of the acute exanthemata, the very elect have gone astray, that hasty judgment may mean long repentance, that twenty-four hours later the question is often answered and that doubtful cases should be isolated and reported promptly to the health authorities.

The initial rashes may lead to error. The scarlatinal rash has rarely the extent and never the persistence of the rash in scarlet fever. The rash of measles has been mistaken for the initial rash of small-pox. The general condition of the patient, the coryza, conjunctivitis and Koplik's sign, may be better guides than the rash itself.

Malignant hæmorrhagic small-pox may prove fatal before the characteristic rash appears. Of 27 cases of purpura variolosa, in only one, in which death occurred on the third day, did inspection fail to show the papules. In 3 cases dying on the fourth day the characteristic papular rash was noticed. It may be difficult or impossible to diagnose this form of hæmorrhagic smallpox from hæmorrhagic scarlet fever or hæmorrhagic measles, though in the latter there is rarely so constant involvement of the mucous membranes.

Naturally enough, as they are allied affections, *chicken-pox* is the disease

which most frequently leads to error. Particularly is this the case in mild epidemics. Any large number of cases of an infectious disease with a pustular eruption occurring in adults is strongly in favor of small-pox. The following points are important. The rash of chicken-pox appears usually in the first 24 hours of illness, first on the trunk, is chiefly on the face and body and is rare on the extremities of the arms and legs. In small-pox the eruption first appears, after 3 to 4 days of illness, on the face and wrists and is more profuse on the limbs than on the body (not if there are very few pocks). Many lesions on the palms and soles are in favor of small-pox. In chicken-pox the eruption comes out in successive crops for 3 to 5 days and pocks of all stages of development are found on the same area. In small-pox the eruption is in one crop over a given area and the lesions appear steadily for 24 to 48 hours (in a general way from above downwards). The lesion in chicken-pox develops rapidly and is mature in 24 hours; several days are required in small-pox. The pock in chicken-pox is thin walled, tense, translucent (at the height), easily broken, and the collapsed vesicle is soft, hence many broken down vesicles are significant. The vesicles are unilocular and are emptied by one puncture; they are more superficial and sometimes look as if they were placed *on* the skin. The areola about them is not so intense or constant. In small-pox the lesion is firm, deep-seated (*in* the skin), not easily ruptured; the vesicle is multilocular and not emptied by one puncture. There is usually a definite areola about it. The shape (chicken-pox more oval, small-pox round) is not a safe guide. The chicken-pox vesicle is rarely umbilicated, the small-pox vesicle often is but this disappears on pustulation. A rash which has matured in 2 days, or is unchanged for some days is not small-pox.

Successful vaccination within five years is against small-pox. But there are mild epidemics in which the diagnosis is only confirmed by the appearance of a severe case of the confluent or hæmorrhagic form.

The disease may be mistaken for *cerebro-spinal fever*, in which purpuric features are not uncommon. A four-year-old child was taken suddenly ill with fever, pains in the back and head, and on the second or third day petechiæ appeared. There were retraction of the head and marked rigidity of the limbs. The hæmorrhages became more abundant; finally hæmatemesis occurred and the child died on the sixth day. At the post mortem there were no lesions of cerebro-spinal fever, and in the deeply hæmorrhagic skin the papules could be readily seen. The post mortem diagnosis of small-pox was confirmed by the mother taking the disease and dying of it.

Pustular Syphilides.—A copious pustular rash may resemble variola, particularly if accompanied by fever, but the history and distribution, particularly the polymorphous character, leave no question as to the diagnosis.

Pustular glanders has been mistaken for small-pox. In an instance in Montreal there was a widespread pustular eruption, thought at first to be small-pox, but the course and the fact that there was glanders among the horses in the stable led to the correct diagnosis. The eruption resembled exactly that described in Rayner's monograph (De la Morve, 1837).

Impetigo contagiosa is stated to have been mistaken for variola.

Specific Test.—Rabbits sensitized to vaccine virus give a marked reaction in 24 to 48 hours after the intradermic injection of small-pox vesicle contents.

The result of inoculation of material from the pocks in the cornea of the rabbit is helpful when positive. The virus of small-pox gives a specific complement fixation and flocculation with an antivariola serum. The reaction is done with a suspension of the crusts from a suspected case and a specific flocculating serum from a rabbit.

Prophylaxis.—Thorough vaccination and re-vaccination are the most important preventive measures. All those exposed to infection should be vaccinated at once, as four days after exposure a successful vaccination may protect from the disease. During epidemics general vaccination of the community should be done and special care taken to recognize mild cases. Those who have been exposed should be isolated for sixteen days. Isolation of those with the disease should be rigid and, if possible, they should be placed in a special hospital. The attendants should wear gowns and caps; rubber gloves are an advantage. The linen should be placed in phenol solution (2 per cent.) and boiled afterwards. Dressings should be burned. The patient should not be discharged until all the crusts are removed; a thorough sponging with phenol solution (2 per cent.) is advisable.

Treatment.—GENERAL CONSIDERATIONS.—Segregation in special hospitals is imperative. In local outbreaks temporary barracks or tents may be used.

We have no specific treatment. There should be abundance of fresh air; the diet should be liquid and large amounts of water and cold drinks given. A calomel and saline purge is advisable at the onset and later the bowels should be kept open by salines. In the early stages two symptoms call for treatment: the pain in the back, which, if not relieved by phenacetine (gr. v, 0.3 gm.), requires opium in some form, as advised by Sydenham; and the vomiting, which is very difficult to check. Nothing should be given except a little ice, and it usually stops with the appearance of the eruption.

For the fever, cold sponging or the tub bath may be used; when there is much delirium with high fever the latter or the cold pack is preferable. In some cases, particularly with severe toxæmia and marked eruption, the continuous warm bath is advisable.

The treatment of the *eruption* is important. After trying all sorts of remedies, such as puncturing the pustules with nitrate of silver, or treating them with iodine and various ointments, Sydenham's conclusion that in guarding the face against being disfigured "the only effect of oils, liniments, and the like was to make the white scurfs slower in coming off" seems correct. The constant application on the face and hands of lint soaked in solutions, such as phenol (2 per cent.), potassium permanganate (1 per cent.) or bichloride of mercury (1 to 5,000) is perhaps the most suitable local treatment. Equal parts of tincture of iodine and alcohol may be applied daily. When the crusts begin to form, the chief point is to keep them thoroughly moist with oil or glycerine. This prevents the desiccation and diffusion of the flakes of epidermis. Vaseline is useful and may be freely used upon the face. Phenol (3 to 5 per cent.) in oil or vaseline may be used and also relieves the itching. For the odor, the dilute phenol solutions are best. When suppuration is marked the continuous warm bath (95°) is useful. Boric acid, alum or potassium permanganate may be added to the water.

The papules do not mature so well when protected from the light, and for centuries attempts have been made to modify the course of the pustules by

either excluding the light or by changing its character. In the Middle Ages John of Gaddesden recommended wrapping the patient in red flannel, and treated in this way the son of Edward I. It was an old practice of the Egyptians and Arabians to cover the exposed parts of small-pox patients with gold-leaf. The red-light treatment of the disease has been advocated by Finsen, but the statements do not agree as to its value. Exposure to violet rays has been advised.

COMPLICATIONS.—If the diarrhoea is severe, paregoric may be given. When the pulse becomes feeble and rapid, stimulants may be freely given. The maniacal delirium may require chloroform or morphia, but for less intense nervous symptoms the bath or cold pack is the best. For the severe hæmorrhages of the malignant cases nothing can be done, and it is only cruel to drench the patient with iron, ergot, and other drugs. Symptoms of obstruction in the larynx, usually from œdema, may call for tracheotomy. In the late stages, if the patient is debilitated and the subject of abscesses and bed-sores, he may be placed on an air bed or treated in the continuous bath.

The care of the *eyes* is most important. The lids should be thoroughly cleansed and the conjunctivæ washed with a warm solution of boracic acid. In the confluent cases the eyelids are swollen and glued together, and only constant watchfulness prevents keratitis. The edges of the lids should be smeared with vaseline. The mouth and throat should be kept clean, a potassium permanganate mouth wash and gargle used, and treatment of the nose with glycerin or oil should be begun early, to prevent the formation of crusts. Douching the nose with a warm alkaline solution is helpful.

The treatment in the stage of convalescence is important. Frequent bathing helps to soften the crusts, and the skin may be oiled daily. Convalescence should not be considered established until the skin is perfectly smooth and clean and free from any trace of scabs.

II. VACCINIA (Cow-pox)—VACCINATION

Definition.—An eruptive disease of the cow, the virus of which, inoculated into man (vaccination), produces a local pock with constitutional disturbance, which affords protection, more or less permanent, against small-pox.

History.—For centuries it had been a popular belief among farmer folk that cow-pox protected against small-pox. The notorious Duchess of Cleveland, replying to some joker who suggested that she would lose her occupation if she was disfigured with small-pox, said that she was not afraid of the disease, as she had had a disease that protected her against small-pox. Jesty, a Dorsetshire farmer, had had cow-pox, and in 1774 vaccinated successfully his wife and two sons. Plett, in Holstein, in 1791, successfully vaccinated three children. When Jenner was a student at Sodbury, a young girl, who came for advice, when small-pox was mentioned, exclaimed, "I cannot take that disease, for I have had cow-pox." Jenner subsequently mentioned the subject to Hunter, who in reply gave the famous advice: "Do not think, but try; be patient, be accurate." As early as 1780 the idea of the protective power of vaccination was firmly impressed on Jenner's mind. The problem was brought to a practical issue when, on May 14, 1796, he took matter from

the hand of a dairy-maid, Sarah Nelves, who had cow-pox, and inoculated a boy named James Phipps, aged eight years. On July 1st, matter was taken from a small-pox pustule and inserted into the boy, but no disease followed. In 1798 appeared An Inquiry into the Causes and Effects of the Variola Vaccinæ, a Disease Discovered in Some of the Western Counties of England, Particularly Gloucestershire, and Known by the Name of Cow-pox (pp. iv, 75, four plates, 4to. London, 1798).

In the United States cow-pox was introduced by Benjamin Waterhouse, Professor of Physic at Harvard, who on July 8, 1800, vaccinated seven of his children. In Boston on August 16, 1802, nineteen boys were inoculated with the cow-pox. On November 9th twelve of them were inoculated with small-pox; nothing followed. A control experiment was made by inoculating two unvaccinated boys with the same small-pox virus; both took the disease. The nineteen children of August 16th were again unsuccessfully inoculated with fresh virus from these two boys. This is one of the most crucial experiments in the history of vaccination, and fully justified the conclusion of the Board of Health—*cow-pox is a complete security against the small-pox*.

Practitioners should familiarize themselves with the literature on vaccination. The centenary number of the British Medical Journal is particularly valuable (1896). The report of the Royal Commission on vaccination (1897), the exhaustive articles in Allbutt and Rolleston's System by T. D. Acland, Copeman and McVail, and Cory's monograph on the subject afford a large body of material. To public health officials who wish for distribution in handy shape "Facts about Small-pox and Vaccination" leaflets issued by the British Medical Association will be of the greatest value. The Vaccination Law of the German Empire, printed in English (Berlin, B. Paul, 1904), contains important information and statistics.

Nature of Vaccinia.—Is cow-pox a separate independent disease, or is it only small-pox modified by passing through the cow? After long controversy the weight of opinion favors the view that cow-pox and horse-pox are variola modified by transmission through the animal; or "small-pox and vaccinia are both of them descended from a common stock—from an ancestor, for instance—which resembled vaccinia far more than it resembled small-pox" (Copeman). The small-pox virus is altered or attenuated so that its usual course, when inoculated into the human individual, is to produce a local lesion only. It is also altered in that its infective powers are altered and it can be conveyed only by inoculation.

The bodies described by Guarnieri have been very thoroughly studied by Councilman and his colleagues, who regard them as forms of protozoön—*Cytoryctes vacciniæ*—with a well characterized development cycle, increasing in size until they undergo segmentation.

Normal Vaccination.—PERIOD OF INCUBATION.—At first there may be a little irritation at the site of inoculation, which subsides.

PERIOD OF ERUPTION.—On the third day, as a rule, a papule is seen surrounded by a reddish zone. This gradually increases, and on the fifth or sixth day shows a definite vesicle, the margins of which are raised while the centre is depressed. By the eighth day the vesicle has attained its maximum size. It is round and distended with a limpid fluid, the margin hard and prominent, and the umbilication is more distinct. By the tenth day the vesicle

is still large and is surrounded by an extensive areola. The contents have now become purulent. The skin is also swollen, indurated, and often painful. On the eleventh or twelfth day the hyperæmia diminishes, the lymph becomes more opaque and begins to dry. By the end of the second week the vesicle is converted into a brownish scab, which gradually becomes dry and hard, and in about a week (that is, about the twenty-first or twenty-fifth day from the vaccination) separates and leaves a circular pitted scar. If the points of inoculation have been close together, the vesicles fuse and may form a large combined vesicle. Constitutional symptoms of a more or less marked degree follow the vaccination. Usually on the third or fourth day the temperature rises, and may persist, increasing until the eighth or ninth day. There is a marked leucocytosis. In children it is common to have with the fever restlessness, particularly at night, and irritability; but as a rule these symptoms are trivial. If the inoculation is made on the arm, the axillary glands may become large and sore; if on the leg, the inguinal glands. Immunity is not necessarily complete at once after vaccination; it may take as long as three weeks; on the other hand, a person exposed to small-pox and successfully vaccinated at once may escape entirely, or the two diseases may run concurrently, with the small-pox much modified. The duration of the immunity is extremely variable. In some instances it is permanent, but a majority of persons within ten or twelve years again become susceptible.

Revaccination should be performed about the ninth or tenth year, and whenever small-pox is epidemic. The susceptibility to revaccination is very general. In 1891-'92 vaccination pustules developed in 88.7 per cent. of the newly enrolled troops of the German army, most of whom had been vaccinated twice in their lives before. The vesicle in revaccination is usually smaller, has less induration and hyperæmia, and the resulting scar is less perfect. Particular care should be taken to watch the vesicle of revaccination, as it not infrequently happens that a spurious pock is formed, which reaches its height early and dries to a scab by the eighth or ninth day.

Irregular Vaccination.—(a) **LOCAL VARIATIONS.**—In occasional instances the vesicle develops rapidly with much itching, has not the characteristic flattened appearance, the lymph early becomes opaque, and the crust forms by the seventh or eighth day. The evolution of the pocks may be abnormally slow. In such cases the operation should again be performed with fresh lymph. The contents of the vesicles may be watery and bloody. In the involution the bruising or irritation of the pocks may lead to ulceration and inflammation. A very rare event is the recurrence of the pock in the same place. Sutton reports four such recurrences within six months.

(b) **ACCIDENTAL VACCINIA.**—The virus may be inoculated in other parts by the fingers: the eyelids, face and genitals are the most common sites. Occasionally, by sucking the vaccinated area to prevent "a take," the lips are inoculated.

(c) **GENERALIZED VACCINIA.**—It is not uncommon to see vesicles in the vicinity of the primary sore. Less common is a true generalized pustular rash, developing in different parts of the body, often beginning about the wrists and on the back. The secondary pocks may continue to make their appearance for five or six weeks after vaccination. They may be most abun-

dant on the vaccinated limb, and occur usually about the eighth to the tenth day.

(d) **COMPLICATIONS.**—In unhealthy subjects, or as a result of uncleanness, or sometimes injury, the vesicles inflame and ulcers result. Sloughing and deep cellulitis may follow. In debilitated children there may be a purpuric rash with this.

(1) During the first three days: Erythema; urticaria; vesicular and bullous eruptions; invaccinated erysipelas.

(2) After the third day and until the pock reaches maturity: Urticaria; lichen urticatus, erythema multiforme; accidental erysipelas.

(3) About the end of the first week: Generalized vaccinia; impetigo; vaccinal ulceration; glandular abscess; septic infections; gangrene.

(4) *Encephalitis*.—Cases of this have been reported in recent years. The incubation period is ten to twelve days with a sudden onset of symptoms, fever, delirium, strabismus and occasionally paralysis of the limbs. The mortality has been high, over 50 per cent. in some series, but complete recovery may occur. The etiology is in doubt; it does not seem to be due to the vaccine virus alone. There is a perivascular and marginal demyelination in the form of a zone around the veins, along the ventral fissure of the cord and beneath the pia and ependyma.

(e) **TRANSMISSION OF DISEASES BY VACCINATION.**—*Syphilis* has very rarely been transmitted by arm to arm vaccination, but a large number of the cases of alleged vaccino-syphilis must be thrown out. The question is now of *no importance* since the general use of animal lymph.

Tuberculosis.—"No undoubted case of invaccinated tubercle was brought before the Royal Commission on Vaccination" (Acland). The risk of transmitting tuberculosis from the calf is so slight that it need not be considered. The transmission of leprosy by vaccination is doubtful. *Actinomyces* has been found in vaccine virus in the past.

Tetanus.—The occurrence of *tetanus* due to inoculation during vaccination is most unlikely with the care taken in the preparation of vaccine matter. The vaccination area may be infected subsequently with tetanus organisms as any other wound.

(f) **INFLUENCE OF VACCINATION UPON OTHER DISEASES.**—A quiescent malady may be lighted into activity by vaccination. This has happened with congenital syphilis, occasionally with tuberculosis. An old idea was prevalent that vaccination had a beneficial influence upon existing diseases. Thomas Archer, the first medical graduate in the United States, recommended its use in whooping-cough, and said that it had cured several cases in his hands.

Technique.—That part of the arm about the insertion of the deltoid or the back and inner side of the upper arm is usually selected. Mothers "in society" prefer to have girl babies vaccinated on the leg. The skin should be cleansed and put upon the stretch. Then, with a scalpel, needle, or the ivory point, superficial incisions should be made in one or more places. Four points of insertion, an inch apart, or two incisions, each about half an inch long and a little less than an inch apart, may be made. The incision should not be deep enough to draw blood in large drops. The virus is rubbed gently into the incisions and allowed to dry. When glycerine lymph is used the drops may be placed on the skin first and the incisions then made. The clothing should not be adjusted until the spot has dried, and it should be protected

for a day or two with lint or a soft handkerchief. Another method is by *acupuncture*. In doing this the vaccine is deposited on the cleaned skin, which is then drawn tight. An ordinary needle is used with the point slanting and nearly parallel with the skin. It is pressed against the skin through the drop of vaccine and a very slight puncture made. Six of these are made in a small space. When the vesicle forms it can be protected by sterile gauze held in place by strapping. Vaccination is usually performed between the fourth and sixth month. If unsuccessful, it should be repeated from time to time. It should be postponed if the child has any ailment or suffers from syphilis or a skin disease. Revaccination should be done at the age of nine years. A person exposed to small-pox should always be revaccinated. This, if successful, will usually protect; but not always. The cases in which small-pox is taken within a few years after vaccination are probably instances of spurious vaccination.

In the *intracutaneous* method, 0.1 c. c. of glycerinated lymph, diluted 3 to 10 times with physiological salt solution, or sterile water, is injected into the skin. The needle should be deep enough not to show through the skin.

The Value of Vaccination.—Sanitation cannot account for the diminution in small-pox and for the low rate of mortality. Isolation is a useful auxiliary but it is no substitute. Vaccination is not claimed to be an invariable and permanent preventive of small-pox, but in an immense majority of cases successful inoculation renders the person for many years insusceptible. Communities in which vaccination and revaccination are thoroughly and systematically carried out are those in which small-pox has the fewest victims. On the other hand, communities in which vaccination and revaccination are persistently neglected are those in which epidemics are most prevalent. Owing to a widespread prejudice against vaccination in Montreal, there grew up, between the years 1876 and 1884, a considerable unprotected population, and the materials were ripe for an extensive epidemic. The soil had been prepared and it only needed the introduction of the seed, which in due time came with the Pullman-car conductor from Chicago, on the 28th of February, 1885. Within the next ten months thousands of persons were stricken with the disease, and 3,164 died. The statistics from Japan, published by Kitasato (1911), show strikingly the efficacy of vaccination in that country. In the Japanese army of more than a million men in a war waged in a country in which small-pox was then epidemic there were only 362 cases and 35 deaths. He shows with great clearness the gradual lessening of the intensity of the epidemics in Japan as the system of vaccination has been perfected.

Although the effects of a single vaccination may wear out, as we say, and the individual again becomes susceptible to small-pox, yet the mortality in such cases is very much lower than in persons who have never been vaccinated. There is evidence that the greater the number of marks the greater the protection; thus, the English Vaccination Report states that out of 4,754 cases the death-rate with one mark was 7.6 per cent.; with two marks, 7 per cent.; with three marks, 4.2 per cent.; with four marks, 2.4 per cent. W. M. Welch's statistics of 5,000 cases on this point give with good cicatrices 8 per cent.; with fair cicatrices, 14 per cent.; with poor cicatrices, 27 per cent.; post-vaccinal cases, 16 per cent.; unvaccinated cases, 58 per cent.

III. VARICELLA (Chicken-pox)

Definition.—An acute contagious disease, characterized by an eruption of vesicles on the skin which appear in successive crops.

History.—Ingrassias, a distinguished Neapolitan professor, first recognized the disease as differing from small-pox (1553). Heberden gave it the name chicken-pox (1767).

Etiology.—The disease occurs in epidemics, but sporadic cases are also met with. Infection is usually direct but may be by fomites. It is a disease of childhood; a majority of the cases occur between the second and sixth years. Adults who have not had the disease in childhood are very liable to be attacked. The specific germ has not been discovered. There are many reports of an association with herpes zoster.

Varicella is an affection distinct from variola and without any relation to it. An attack of the one does not confer immunity to the other. A boy, aged five, was admitted to St. Thomas' Hospital with a vesicular eruption, and isolated in a ward on the same floor as the small-pox ward. The disease was pronounced chicken-pox by Risdon Bennett and Bristowe. The patient was then removed and vaccinated with a result of four vesicles which ran a pretty normal course. On the eighth day from the vaccination the child became feverish. On the following day papules appeared and the child had a well-developed attack of small-pox (Sharkey).

Symptoms.—After a period of incubation of ten or fifteen days the child becomes feverish and in some instances has a slight chill. Prodromal rashes may occur, usually erythematous but sometimes like measles. There may be vomiting, and pains in the back and legs. Convulsions are rare. The eruption usually appears within twenty-four hours. It is first seen upon the trunk, either on the back or on the chest. It may begin on the forehead and face. At first in the form of macules, then raised red papules, these are in a few hours transformed into hemispherical vesicles containing a clear or turbid fluid. Many are translucent and seem to be *on* rather than *in* the skin. As a rule there is no umbilication, but in rare instances the pocks are flattened, and a few may even be umbilicated. They are often ovoid in shape and look more superficial than the variolous vesicles. The contents are in one chamber and the pock collapses on puncture. The skin in the neighborhood is not often infiltrated or hyperæmic. At the end of thirty-six or forty-eight hours the contents of the vesicles are purulent. They begin to shrivel, and during the third and fourth days are converted into dark brownish crusts, which fall off and as a rule leave no scar. Fresh crops appear during the first two or three days of the illness, so that on the fourth day one can usually see pocks in all stages of development and decay. They are always discrete, and the number may vary from eight or ten to several hundreds. The rash is most profuse on the trunk, particularly on the back. On the arms and legs it is scanty on the distal portions. The eruption may occur on the mucous membrane of the mouth, and occasionally in the larynx. In adults the disease may be severe, the initial fever high, the rash very widespread, and the constitutional symptoms marked, so that the diagnosis of small-pox may be made. The fever in varicella is slight, but it does not as a rule disappear with the

appearance of the rash. The course is favorable in a large majority of the cases and no ill effects follow. The disease may recur in the same individual.

There are occasional modifications of the rash. The vesicles may become very large and develop into *bullæ*, looking not unlike ecthyma or pemphigus (varicella bullosa). The irritation of the rash may be excessive, and if the child scratches the pocks ulcerating sores may form, which leave scars on healing. Cicatrices after chicken-pox are more common than after varioloid. In delicate children, particularly the tuberculous, *gangrene* (varicella escharotica) may occur about the vesicles, or in other parts, as the scrotum. Cases of *hæmorrhagic* varicella have been described with cutaneous ecchymoses and bleeding from the mucous membranes.

Nephritis may occur. Infantile hemiplegia has occurred during an attack and neuro-retinitis has been noted. Death has followed from extensive involvement of the skin. Encephalitis has been reported.

Diagnosis.—The diagnosis is as a rule easy, particularly if the patient has been seen from the onset. When a case comes under observation for the first time with the rash well out, there may be considerable difficulty. The abundance of the rash on the trunk in varicella is most important. The pocks in varicella are more superficial, more bleb-like, have not so deeply an infiltrated areola about them, and may usually be seen in all stages of development. They rarely at the outset have the hard, shotty feeling of those of small-pox. The general symptoms, the greater intensity of the onset, the prolonged period of invasion, and the more frequent occurrence of prodromal rashes in small-pox are important points in the diagnosis.

Prognosis.—Death is very rare, and, unless from the complications, raises a suspicion of the correctness of the diagnosis. Thus of the 49 deaths in England and Wales in 1928 ascribed to chicken-pox, it is probable that some were from unrecognized small-pox.

Vaccination from the vesicles seems to have decreased the incidence in those exposed to infection. Convalescent serum (10-15 c. c. intramuscularly) obtained within a month of the attack is an efficient preventive.

No special *treatment* is required. If the rash is abundant on the face, care should be taken to prevent the child from scratching the pustules. A soothing lotion or phenol (3 to 5 per cent.) in vaseline should be applied.

IV. MEASLES (Morbilli)

Definition.—An acute, highly infectious fever with specific localization in the upper air passages and in the skin.

As a cause of death measles ranks high among the fevers of children. In 1915 there were 16,445 deaths from this disease in England and Wales, but only 4,302 deaths in 1928. In the U. S. registration area there were only 2,404 deaths in 1925. The death-rate is highest in the second year.

History.—Rhazes, an Arabian physician, in the ninth century described the disease with small-pox, of which it was believed to be a mild form until Sydenham separated them in the seventeenth century.

Etiology.—The liability to infection is almost universal in persons unprotected by a previous attack. It is a disease of childhood, but in the wide-

spread epidemics in the Faroe and Fiji Islands, unprotected adults of all ages were attacked. Within the first three months of life there is a relative immunity. Occasionally infants of a month or six weeks take the disease. Intra-uterine cases have been described, and a mother with measles may give birth to a child with the eruption, or the rash may appear in a few days.

The disease is endemic in cities, and becomes epidemic at intervals of a few years, prevailing most extensively in the cooler months, though this is by no means a fixed rule.

The germ of the disease is unknown. J. F. Anderson has shown that the blood of a patient inoculated into the Rhesus monkey produces after eight days a fever of short duration with a well-marked slight exanthem. The agent is present in the blood, the secretions of the mouth and nose, and in the skin. In the eighteenth century Monro and others demonstrated the inoculability of the disease. Direct infection is the most common. The poison is probably not in the expired air, but in the particles of mucus and in the sputum and the secretions of the mouth and nose, which, dried, are conveyed with dust. An important point is the infectiousness of the disease in the pre-eruptive stage. A child with catarrhal symptoms only may be at school and a source of active infection. Indirect infection by means of fomites is not very common. The work of Tunncliffe suggests a diplococcus as the causal organism.

Recurrence is rare. Many cases of supposed second and third attacks represent mistakes in diagnosis. Relapse is occasionally seen, the symptoms recurring at intervals from ten to forty days.

Morbid Anatomy.—The catarrhal and inflammatory appearances seen post mortem have nothing characteristic. Fatal cases show, as a rule, bronchopneumonia and an intense bronchial catarrh. The lymphatic elements all over the body are swollen, the tonsils, the lymph-glands, and the solitary and agminated follicles of the intestines. The spleen is rarely much enlarged. During convalescence latent tuberculous foci are very apt to become active. Encephalitis with punctate hæmorrhages may occur.

Symptoms.—**INCUBATION.**—"From seven to eighteen days; oftenest fourteen." The child shows no special changes, but coryza and swelling of the cervical lymph-glands may be present. A polynuclear leucocytosis may be present.

INVASION.—In this period, lasting from three to four days, very rarely five or six, the child presents the symptoms of a feverish cold. The onset may be insidious, or it may start with great abruptness, even with a convulsion. There is not often a definite chill. Headache, nausea, and vomiting may usher in the severe cases. The common catarrhal symptoms are sneezing and running at the nose, redness of the eyes and lids, and cough. The fever is slight at first, but gradually there is pungent heat of the skin with turgescence of the face. Prodromal rashes precede the eruption in a few cases, usually a blotchy erythema or scattered macules. The tongue is furred and the mucous membranes of the mouth and throat are hyperæmic, and frequently show a distinct punctiform rash. The fever of the stage of invasion may rise abruptly; more frequently it takes 24 or 48 hours to reach the fastigium. The pulse-rate increases with the fever ($104-105^{\circ}$), and may reach 140 or 160 per minute, gradually falling with defervescence.

ERUPTION.—The general features become more severe as the time of eruption approaches and especially if the eruption is delayed. The respirations may be rapid and slight cyanosis may be present. The rash appears first on the forehead and behind the ears. It spreads rapidly over the neck, body and extremities and is usually fully developed in two or three days. The first stage is a macular eruption which becomes maculo-papular and the lesions often join to form irregular crescentic areas. The rash has a mottled blotchy character. The face is usually swollen and congested and with the catarrhal features has a characteristic appearance. Photophobia is common at this stage. The rash is often more intense on the face than on the trunk and extremities but it may be confluent over the greater part of the body. The general features do not lessen with the appearance of the rash but persist until the fifth or sixth day; the temperature then falls rapidly. The rash usually persists for two or three days and fades rapidly, but instances of longer

CHART X.—MEASLES.

duration are not uncommon. It is hyperæmic and disappears on pressure, but in the malignant cases it may become of a deep rose, inclining to purple. Among peculiarities of the rash are the occurrence of numerous miliary vesicles and of petechiæ, seen occasionally even in cases of moderate severity. Recession of the rash, so much dwelt upon by older writers, is rarely seen. In reality it is the failing circulation which causes the rash to fade.

Measles Line.—About the time of the onset of fever a line of congestion may be found on the lower eyelid about the margin of the cartilage (Stimson, 1928). It should be well marked to be suggestive and it is soon obscured by the general conjunctivitis.

BUCCAL SPOTS were described by Filatow in 1895, and by Koplik in 1896. They are seen on a level with the bases of the lower milk molars on either side, or at the line of junction of the molars when the jaws are closed. They are white or bluish-white specks, surrounded by red areolæ, and are best seen by daylight. Their importance depends upon their early appearance, three days before the skin rash, and remarkable constancy—six-sevenths of all cases. Macules may be seen on the soft palate.

The fauces may be injected, and there is sometimes an eruption of scat-

tered spots over the entire mucous membrane of the mouth. Ringer called attention to opaque white spots on the mucous membrane of the lips.

DESQUAMATION.—After the rash fades desquamation begins, usually in the form of fine scales, more rarely in large flakes. It bears a definite relationship to the extent and intensity of the rash. In mild cases desquamation may take only a few days, in severe cases several weeks.

The tonsils and the cervical lymph glands may be slightly swollen and sore; sometimes there is a polyadenitis. The *spleen* may be enlarged at the height of the eruptive stage; it subsides rapidly.

During the course there is leucopenia with a high proportion of mononuclears, and myelocytes are often present in small numbers during the eruption (Tileston). Leucocytosis suggests a complication.

Atypical Measles.—Variations in the course of the disease are not common. There is an *attenuated* form, in which the child may be well by the fourth or fifth day, and an *abortive* form, in which the initial symptoms may be present, but no eruption appears—*morbilli sine morbillis*.

Malignant or *black measles* is seen most frequently in the widespread epidemics, but it is also met with in institutions, and occasionally in general practice. Hæmorrhages occur into the skin and from the mucous membranes, there is high fever, and the features of profound toxæmia, often with cyanosis, dyspnœa, and extreme cardiac weakness. Death may occur from the second to the sixth day.

Complications.—Those of the air passages are the most serious. The *coryza* may become chronic and lead to irritation of the lymphoid tissues of the naso-pharynx, causing enlarged tonsils and adenoids, and probably leaving these parts less able to resist tuberculous invasion. *Epistaxis* is sometimes serious. *Laryngitis* is not uncommon: the voice becomes husky and the cough croupy in character. (Edema of the glottis and pseudo-membranous inflammation are rare. Ulceration, abscess, and perichondritis may occur.

Bronchitis and Broncho-pneumonia.—In every severe case there is the possibility of the bronchitis extending to the small tubes and causing broncho-pneumonia. It is more apt to occur at the height of the eruption or as desquamation begins. The high mortality in institutions is due to this complication, which, as Sydenham remarked, kills more than the small-pox. *Lobar pneumonia* is less common. Venous *thrombosis* has occurred.

Severe *stomatitis* may follow the slight catarrhal form. In institutions *cancrem oris* or *gangrenous stomatitis* is a terrible complication. *Parotitis* occasionally occurs. *Enteritis* and *acute colitis* occur in some epidemics.

Nephritis is less rare than is stated. It is not very uncommon to see cases of chronic nephritis which date from an attack of measles. *Vulvitis* may be present as part of the general catarrhal condition.

Endocarditis is rare. *Arthritis* may be general and severe, and in one instance ankylosis of the jaw followed an attack of measles in a child of four years. The conjunctivitis may be followed by *keratitis*. Optic neuritis and atrophy may occur. *Otitis media* is not uncommon and may lead to perforation of the drum or mastoid disease. *Hemiplegia* is a most serious complication and usually persists. *Encephalomyelitis* shows drowsiness or stupor, possibly with convulsions, and signs of meningitis. With special spinal involvement there may be paraplegia with loss of sphincter control.

Polyneuritis may occur with widespread atrophy. Acute mania, *meningitis*, *abscess of the brain*, and *multiple sclerosis* are among the rare complications or sequelæ. *Scarlet fever* may occur with measles. *Whooping-cough* not infrequently follows measles.

Diagnosis.—During the prevalence of an epidemic the disease is easily recognized. At the onset the catarrhal symptoms may be regarded as a simple coryza or if laryngitis is marked, diphtheria may be suspected. In early stages, œdema of the palpebral conjunctivæ is important. Physicians to isolation hospitals appreciate the difficulties and patients with measles may be sent to the small-pox hospital; it is well to bear in mind that in adults, especially negroes, the beginning of the eruption on the face, its nodular character, and the isolation of the spots may be suggestive of variola. From *scarlet fever* measles is distinguished by the longer initial stage with characteristic symptoms, and the blotchy irregular character of the rash, so unlike the diffuse uniform erythema. In measles the mouth (with the early Koplik sign), in scarlet fever the throat, is chiefly affected. Occasionally in measles, when the throat is very sore and the eruption diffuse, there may at first be difficulty in determining which disease is present, but a short interval makes the diagnosis clear. As a rule there is no leucocytosis. It may be extremely difficult to distinguish from *rubella*. The shorter prodromal stage, the absence of oculo-nasal catarrh, and the slighter fever in many cases are perhaps the most important features. It is difficult to speak definitely about distinctions in the rash, though perhaps the more uniform distribution and the absence of the crescentic arrangement are more constant in *rubella* in which adenitis is more marked. The distribution of the rash, the coryza, and the rash in the mouth are important points. Of *drug* eruptions, that due to *copaiba* is very like measles, but is distinguished by the absence of fever and catarrh. Antipyrin, chloral, and quinine rashes rarely cause any difficulty. A serum exanthem may be difficult to distinguish. In adults acute malignant measles may resemble typhus fever, especially when the rash is dusky, but in typhus fever the rash is rarely on the face and always is in measles. Occasionally erythema multiforme simulates measles.

The lesions of Fordyce's disease may be mistaken for Koplik spots. This is a chronic disease of the mucous membrane of the mouth and lips, with white and yellow lesions, pin-point to pin-head in size, on the buccal mucous membrane opposite the line of the teeth back to the last molar.

Prognosis.—The mortality from the disease itself is not high, but the pulmonary complications render it one of the most serious of the diseases of children. In some epidemics, the death-rate may be high, not so much from the disease itself as from the broncho-pneumonia. Imported in 1875 from Sydney by H. M. S. *Dido* to the Fiji Islands, 40,000 out of 150,000 of the inhabitants died in four months. Panum, the distinguished Danish physician, described the widespread and fatal epidemic which decimated the inhabitants of the Faroe Islands in 1846. In private practice the mortality is from 2 to 3 per cent.; in hospitals from 6 to 8 or 10 per cent.

Prophylaxis.—The difficulty is inherent in the prolonged incubation and the period of invasion, during which the catarrhal symptoms are marked, and the disease is infectious, and one often finds that the quarantine which has been carried out has been in vain. From contact with cases in the stage

of invasion and mild cases with scarcely any fever the disease is readily disseminated through schools and conveyed to healthy children in the everyday contact with each other. The patient should be carefully quarantined and all possible precautions taken against the spread of the disease in the house. The deliberate exposure of children to infection should be strongly forbidden. The usual quarantine period is for fourteen days after the appearance of the rash, unless there is cough or discharge from the nose or ears. The blood serum of convalescents taken 5 to 10 days after the temperature is normal is used in prevention, 2.5 c. c. being given for the first four days after exposure and 5 c. c. on the fifth and sixth days. Small doses (2.5 c. c.) are given from the fifth to the tenth day to modify the attack. Larger doses should be given for children over three years of age.

Treatment.—Confinement to bed in a well-ventilated room, a liquid diet with fruit juices, ice cream and abundance of water and a simple fever mixture are the only measures necessary in ordinary cases. If there is photophobia the light should be cut off and the eyes bathed with boric acid solution. The fever rarely reaches a dangerous height. If it does it may be lowered by sponging or by the tepid bath gradually reduced. If the rash does not come out well, warm drinks and a hot bath will hasten its maturation. The bowels should be freely opened. If the cough is distressing compresses should be applied to the chest and inhalations of the compound tincture of benzoin or small doses of paregoric or codein given. The patient should be kept in bed for a few days after the fever subsides. During desquamation the skin should be oiled daily, and warm baths given to facilitate the process. The mouth and nostrils should be carefully cleansed, even in mild cases. The reports of the use of convalescent serum (10-20 c. c.) suggest that it has some value. It apparently does not influence the complications. The convalescence is a most important stage and watchfulness and care may prevent serious pulmonary complications. The frequency with which the mothers of children with simple or tuberculous broncho-pneumonia tell us that "the child caught cold after measles," and the contemplation of the mortality bills, should make us extremely careful in our management of this affection.

V. RUBELLA (German Measles)

Definition.—This is an exanthem with features resembling both scarlet fever and ordinary measles but is a distinct and separate disease.

Etiology.—It is propagated by infection and spreads with great rapidity. It frequently attacks adults, and the occurrence of measles or scarlet fever in childhood is no protection against it. The epidemics of it are often very extensive. The causal organism is not known, but it is probably given off from the respiratory tract and mouth.

Symptoms.—These are usually mild, and it is altogether a less serious affection than measles. Very exceptionally, the symptoms are severe. The stage of incubation is two weeks or even longer. There may be a short prodromal stage, not over 24 hours, with slight catarrhal symptoms, perhaps headache and malaise. The rash appears on the first or second day, usually first on the face or neck, spreading rapidly to the trunk and limbs and being

general within 24 hours. The eruption consists of round or oval, slightly raised spots, pinkish red in color, sometimes discrete but often confluent. The rash resembles that of measles in its early stages and later may become more like that of scarlet fever. At times it has some resemblance to both diseases. The rash commonly lasts for two or three days, fades gradually, and there is usually a fine desquamation. The throat shows a macular, rose-red eruption, which may involve the soft palate, and the tonsils may be swollen and red. Koplik's spots do not occur. *Adenitis* is a characteristic feature, the occipital and posterior cervical glands being enlarged and tender. Occasionally the axillary and inguinal glands are involved also. The swelling may persist for some time. The fever is usually slight and rarely persists for more than two or three days.

There are no special complications. The disease usually progresses favorably; but in rare instances the symptoms are of greater severity. Albuminuria, arthritis, or nephritis may occur. Pneumonia and colitis have been present in some epidemics. Icterus has been seen.

Diagnosis.—The slowness of the prodromal symptoms, the mildness or the absence of the fever, the more diffuse character of the rash, its rose-red color, and the early enlargement of the cervical glands, are the chief points of distinction from measles. From scarlet fever, it is distinguished by the absence of the severe symptoms of onset and specific skin tests, slight fever, absence of a rapid pulse rate, adenitis, and mixed character of the rash.

The treatment is that of a simple febrile affection.

"Fourth Disease."—Clement Dukes described a "fourth disease," in which the body is covered in a few hours with a diffuse exanthem of a bright red color, almost scarlatiniform in appearance. The face may remain quite free. The desquamation is more marked than in rubella. There is doubt as to this being a distinct disease.

Erythema Infectiosum.—This is a feebly infectious disease occurring usually in children but also in adults. The incubation is from seven to fourteen days. The onset is with malaise, headache, and vomiting. The rash is variable and polymorphous. The face may be specially involved but there may be circumoral pallor. There is erythema with swelling of the skin, suggesting urticaria. The distribution over the trunk and limbs is variable. The eruption may disappear and recur. There may be slight bronchitis and conjunctivitis. Fever is usually slight. The spleen may be enlarged. The blood shows a leucopenia with lymphocytosis and sometimes eosinophilia. The treatment is symptomatic.

VI. EPIDEMIC PAROTITIS (Mumps)

Definition.—A specific infectious disease, characterized by swelling of the salivary glands, especially the parotid, and a liability to orchitis in males.

Hippocrates described the disease and its peculiarities—an affection of children and young male adults, the absence of suppuration, and the orchitis.

Etiology.—The nature of the virus is not proved; various organisms have been described. It is endemic in large centres of population, and at certain seasons, particularly spring and autumn, the cases increase rapidly. It is

met most frequently in childhood and adolescence. Very young infants and adults are seldom attacked. Males are somewhat more frequently affected than females. In institutions, barracks, and schools the disease has been known to attack over 90 per cent. of the residents. It may be curiously localized in a city or district, or even in one part of a school or barrack. Mumps was very prevalent in the U. S. Army during the great war with 231,490 cases. The infection may persist as long as six weeks. It is probably conveyed by droplet infection from the mouth and nose. The agent is a filter passing virus. It may be congenital, and Hale White reported a case in which the mother and her new-born child were attacked at the same time.

A remarkable idiopathic, non-specific parotitis may follow injury or disease of the abdominal or pelvic organs (see Diseases of the Salivary Glands).

Foci of acute interstitial inflammation have been found post-mortem.

Symptoms.—The period of incubation is from two to three weeks, and there are rarely any symptoms during this stage. The invasion is marked by fever, which is usually slight, rarely rising above 101° , but an exceptionally severe case reaches 103° or 104° F. The child complains of pain just below the ear on one side, most often the left, where a slight swelling is noticed, which increases gradually, and within forty-eight hours there is great enlargement of the neck and side of the cheek. The swelling passes forward in front of the ear, the lobe of which is lifted, and back beneath the sterno-mastoid muscle. It fills the space between the jaw and the mastoid process. The other side usually becomes affected within a day or two, and the whole neck is surrounded by a collar of doughy infiltration. Only one gland is involved in about one-third of the cases; an interval of four or five days may elapse before the other side is involved. The submaxillary and sublingual glands may become swollen; in a few cases they may be alone attacked. The lachrymal glands may be involved and the tonsils swollen. The greatest inconvenience is experienced in taking food, for the patient is unable to open the mouth, and even speech and deglutition become difficult. There may be an increase in the secretion of the saliva, but the reverse is sometimes the case. The mucous membrane of the mouth and throat may be slightly inflamed. There is seldom great pain, but an unpleasant feeling of tension and tightness. There may be earache, even otitis media, and slight impairment of hearing. There is usually a slight leucocytosis with relative increase in the lymphocytes, changing to a polynuclear increase with orchitis.

After persisting for from seven to ten days, the swelling gradually subsides and the child rapidly regains his strength. Occasionally the disease is very severe and characterized by high fever, delirium, and great prostration. The patient may even lapse into a typhoid condition.

Relapse is rare, but there may be two or three slight recurrences within a few weeks, in which the cervical glands may enlarge. A second or even a third attack may occur but one attack usually gives immunity.

Orchitis.—Excessively rare before puberty, it occurs usually about the eighth day, and more particularly if the boy is allowed to leave his bed. One or both (5 to 10 per cent.) testicles may be involved. The swelling may be great, and occasionally effusion takes place into the tunica vaginalis. The orchitis may occur before the parotitis, or in rare instances may be the only manifestation of the infection (*orchitis parotideae*). The inflammation in-

creases for three or four days, and resolution takes place gradually. There may be a muco-purulent discharge from the urethra. In severe cases atrophy may follow, fortunately as a rule only in one organ; occurring in both before puberty, the natural development is usually checked. The atrophy is often slight and may be transient. Even when both testicles are atrophied and small, sexual vigor may be retained. The proportion of cases of orchitis varies in different epidemics from 10 to 20 per cent.; 103 cases of atrophy followed 163 instances of orchitis (Comby). No satisfactory explanation of this metastasis has been given. The transference of the virus to the penis with the fingers and its transmission along the urethra has been suggested. A vulvo-vaginitis sometimes occurs in girls, and the breasts may become enlarged and tender. Mastitis has been seen in boys. Involvement of the ovaries is rare. Acute *pancreatitis* occurs rarely and has been found at operation and autopsy. Acute abdominal pain, nausea and vomiting, tenderness and possibly swelling in the epigastrium, with occasionally fatty stools, are the features. Transient glycosuria has followed. Fortunately recovery is the rule.

Complications and Sequelæ.—Of these the cerebral affections are perhaps the most serious. There may be delirium and signs of meningeal irritation with changes in the spinal fluid, but actual meningitis is rare. Hemiplegia and aphasia may occur. A majority of the fatal cases are associated with meningeal symptoms which are rare in comparison with the frequency of the disease. Acute mania has occurred, and there are instances on record of insanity following the disease.

Arthritis, albuminuria, nephritis, with acute uræmia and convulsions, endocarditis, pleurisy, facial paralysis, and peripheral neuritis are occasional complications. Suppuration of the gland is extremely rare. Gangrene has occasionally occurred. The special senses may be seriously involved. Deafness may occur and be permanent. Affections of the eye are rare, but optic neuritis with atrophy has been described. Thyroiditis may occur.

Chronic hypertrophy of the gland may follow.

Diagnosis.—During an epidemic this is usually easy except in cases in which other salivary glands are involved or orchitis occurs before the parotitis. The non-specific forms of parotitis rarely cause difficulty. Marked swelling of the cervical glands with cellulitis has been mistaken for mumps but the position of the swelling should prevent error. Inflammation of the parotid in children is rare apart from mumps.

Treatment.—It is well to keep the patient in bed for two weeks. This is especially important in males to lessen the chance of orchitis. Isolation for four weeks is advisable. Special care should be given to the mouth by cleaning after feeding and the use of alkaline antiseptic solutions. The bowels should be freely opened, and the patient given a liquid diet. No medicine is required unless the fever is high, in which case acetyl-salicylic acid may be given. Cold compresses may be placed on the gland, but children, as a rule, prefer hot applications. Belladonna or ichthyol ointment is sometimes useful. Suppuration is very rare. With delirium and head symptoms the ice-cap may be applied and sedatives given. For the orchitis, rest, with support and protection of the swollen gland with cotton-wool, is usually sufficient. Non-immune contacts should be isolated for three weeks.

VII. TYPHUS FEVER

Definition.—An acute infectious disease characterized by sudden onset, maculated and hemorrhagic rash, nervous symptoms, and a course terminating by rapid lysis, usually about the end of the second week.

The disease is known by the names of hospital fever, spotted fever, jail fever, camp fever, and ship fever, and in Germany is called *exanthematic typhus*, in contradistinction to *abdominal typhus* (typhoid). The word signifies “smoke” or “mist” in Greek and was used by Hippocrates to describe any condition with a tendency to stupor. In the eighteenth century the name was given by de Sauvages to the common putrid or pestilential fever, and the general use came in through its adoption by Cullen.

Etiology.—Typhus has been one of the great *epidemics* of the world, whose history, as Hirsch remarks, is written in those dark pages which tell of the grievous visitations of mankind by war, famine, and misery. Ireland was terribly scourged by the disease between the years 1817 and 1819, and again in 1846. It prevailed extensively in all the large cities of Great Britain and the Continent. In 1875 in England and Wales there were 1,499 deaths from the disease, but of late years the deaths have been few. It is endemic in parts of Russia and in the Balkan States and there were extensive epidemics in the recent war and have been since.

Sporadic typhus fever offers peculiarities which make its recognition difficult. There may be outbreaks of a few cases, the origin of which may be very difficult to trace. It is not infrequent along the Atlantic coast of the United States. Brill drew attention to this sporadic form in New York. The typhus fever prevailing in Mexico, known as Tabardillo, is more severe, and in its study Ricketts, of Chicago, fell a victim.

The disease is transmitted by the body louse and possibly by the head louse and so is associated with filth and overcrowding. Cases have been reported in the Southern United States by Allan and others in which lice apparently played no part in transmission. Maxcy suggests that there is a source of infection other than man and that this may be in rodents. In epidemics it is one of the most dangerous of all diseases, and those in attendance upon patients are in danger unless special precautions are taken to guard against lice. In a period of twenty-five years in Ireland, among 1,230 physicians attached to institutions, 550 died of this disease. The disease has been transmitted to animals.

Various organisms have been described. The work of the Red Cross Commission (Wolbach, Todd and Palfrey) strongly supports the view that *Rickettsia prowazeki* is the causal organism. The *Rickettsia* have been demonstrated in human and guinea-pig tissues. In the human lesions they have been found in all the tissues in which changes occur. The *Rickettsia* bodies are bacterium-like, very small, occur in pairs and are difficult to stain. A curious phenomenon is the agglutination of a proteus bacillus (x 19) by the serum of typhus fever patients in high dilutions. This organism is not regarded as a cause of the disease. This reaction appears by the fifth day in almost half the cases.

Pathology.—The gross changes are not characteristic. The hæmorrhagic lesions are present in the skin. The viscera show parenchymatous changes but there are no characteristic changes in the bowel. The vessels of the brain may show perivascular hæmorrhage. Endothelial proliferation is common in the small arteries and arterioles, often causing thrombosis. The lesions in the skin are marked; in early stages there is swelling of the endothelium in the small vessels. There is a distinctive perivascular infiltration which is characteristic.

Symptoms.—**INCUBATION.**—This is placed at about twelve days, but it

CHART XI.—TYPHUS FEVER (Murchison).

may be less. There may be ill-defined feelings of discomfort. As a rule, however, the *invasion* is abrupt and marked by chills, followed by fever. The chills may recur during the first few days, and there is headache with pains in the back and legs. There is early prostration, and the patient takes to his bed at once. The temperature is high at first, and may attain its maximum on the second or third day. The pulse is full, rapid, and not so frequently dicrotic as in typhoid. The tongue is furred and white, and there is an early tendency to dryness. The face is flushed and the eyes congested. Vomiting may be a distressing symptom. In severe cases mental symptoms are present from the outset, either a mild febrile delirium or an excited, active, almost maniacal condition. Bronchial catarrh is common and the respiration rate is increased.

STAGE OF ERUPTION.—From the third to the fifth day the eruption ap-

pears—first upon the abdomen and upper part of the chest, and then upon the back and extremities; occurring so rapidly that in two or three days it is general. There are two elements in the eruption: a subcuticular mottling, “a fine, irregular, dusky red mottling, as if below the surface of the skin some little distance, and seen through a semi-opaque medium” (Buchanan); and distinct papular rose-spots which change to petechiæ. In some instances the petechial rash comes out with the rose-spots. Collie describes the rash as consisting of three parts: rose-colored spots which disappear on pressure, dark-red spots which are modified by pressure, and petechiæ upon which pressure produces no effect. In children the rash at first may present a striking resemblance to that of measles and give as a whole a curiously mottled appearance to the skin. The term mulberry rash is sometimes applied to it. In mild cases the eruption is slight, but even then is largely petechial in character. As the rash is hæmorrhagic, it does not disappear after death. Usually the skin is dry, so that sudaminal vesicles are not common. It is stated by some authors that a distinctive odor is present. During the second week the general symptoms are much aggravated. The prostration becomes more marked, the delirium more intense, and the fever rises. The patient lies on his back with a dull, expressionless face, flushed cheeks, injected conjunctivæ, and contracted pupils. The pulse increases in frequency and is feebler; the face is dusky, and the condition becomes more serious. Retention of urine is common. Coma-vigil is frequent, a condition in which the patient lies with open eyes, but quite unconscious; with it there may be subsultus tendinum and picking at the bedclothes. The tongue is dry, brown, and cracked, and there are sordes on the teeth. Respiration is accelerated, the heart’s action becomes more and more enfeebled, and death takes place from exhaustion. In favorable cases about the end of the second week the temperature falls and reaches normal in two or three days. Although the prostration may be extreme convalescence is rapid and relapse very rare. This fairly rapid termination is in striking contrast to the mode of termination in typhoid fever.

FEVER.—The temperature rises steadily during the first four or five days, and the morning remissions are not marked. The maximum is usually attained by the fifth day, when the temperature may be 105° to 107° F. In mild cases it seldom rises above 103° F. After reaching its maximum the fever generally continues with slight morning remissions until the twelfth or fourteenth day. Preceding a fatal termination, there is usually a rapid rise in the fever to 108° or 109° F.

The heart may show signs of weakness. The first sound becomes feeble and almost inaudible, and a systolic murmur at the apex is not infrequent. Hypostatic congestion of the lungs occurs in severe cases. The brain symptoms are usually pronounced and delirium is common. A slight leucocytosis is common and eosinophiles are absent. The frequent arterial thrombosis may involve visceral arteries or cause necrosis and gangrene of the skin.

The urine shows the usual febrile characteristics. Albumin is present in a large proportion of the cases, but nephritis seldom occurs.

Variations in the course of the disease are naturally common. There are malignant cases which rapidly prove fatal within two or three days; the so-called *typhus siderans*. On the other hand, during epidemics there are

extremely mild cases in which the fever is slight, the delirium absent, and convalescence is established by the tenth day.

Sporadic Form.—Beginning with the usual prodromes, the fever increases rapidly and reaches a maximum about the third or fourth day, where it remains fairly constant between 103° and 104° . On the 5th or 6th day an eruption appears, maculo-papular in type, dull red in color, rarely hæmorrhagic, not appearing in crops, not disappearing on pressure, and neither profuse as in measles nor diffuse as in typical typhus; there may be only a few hundred spots. The rash persists until the crisis and then fades rapidly. The patients are much prostrated, with severe headache, but no abdominal symptoms. Constipation is usually a marked feature. After persisting for 12 to 15 days, the fever declines rapidly, usually with a critical fall, and there is a speedy convalescence. It is rarely fatal.

Complications and Sequelæ.—Broncho-pneumonia is perhaps the most common complication. It may pass on to gangrene. In certain epidemics gangrene of the feet, the hands, or the nose, and in children noma or cancrum oris have occurred. Meningitis is rare. Paralyses, which are probably due to cerebral thrombosis or embolism, are not very uncommon. Septic processes, such as parotitis and abscesses in the subcutaneous tissues and in the joints, are occasionally met with. Hæmatemesis may occur.

Prognosis.—The mortality ranges in different epidemics from 12 to 50 per cent. It is very slight in the young. Children, who are quite as frequently attacked as adults, rarely die. After middle age the mortality is high, in some epidemics 50 per cent. Death usually occurs toward the close of the second week and is due to toxæmia or pneumonia.

Diagnosis.—During an epidemic there is rarely any doubt, for the disease presents distinctive general characters. Isolated cases and the form described by Brill may be very difficult to distinguish from typhoid fever. While in typical instances the eruption in the two affections is very different, yet taken alone it may be deceptive, since in typhoid fever a roseolous rash may be abundant and there may be occasionally a subcuticular mottling and even petechiæ. The difference in the onset, particularly in the temperature, is marked; but cases in which it is important to make an accurate diagnosis are not usually seen until the fourth or fifth day. The suddenness of the onset, the greater frequency of the chill, and the early prostration and toxæmia are the distinctive features in typhus. It is easy to put down on paper elaborate differential distinctions, which are practically useless at the bedside. The Widal reaction and blood cultures are important aids. Severe *cerebro-spinal fever* may closely simulate typhus at the outset, but the diagnosis is usually clear within a few days. Malignant *variola* also has certain features in common with severe typhus, but the greater extent of the hæmorrhages and the bleeding from the mucous membranes make the diagnosis clear within a short time. The rash at first resembles that of *measles*, but in the latter the eruption is brighter red, often crescentic or irregular in arrangement, and appears first on the face. *Rocky Mountain Spotted Fever* may resemble typhus fever but the onset is more gradual, the rash usually appears first on the ankles and wrists and the course is longer.

Weil-Felix Reaction.—This depends on the agglutinating power of blood serum from typhus fever patients on a strain of *B. proteus* known as x 19,

which is found in the urine of patients with the disease. The agglutination occurs in high dilutions and is usually present by the fifth or sixth day.

Prophylaxis.—This involves measures against lice, and those attending patients should take special precautions to prevent infection by lice and wear louse-proof clothing. The patient's clothing should be sterilized by heat. Removal of the patient to an isolation hospital is important.

Treatment.—The general management is like that of typhoid fever. Hydrotherapy should be thoroughly and systematically employed; water should be given freely. Medicinal antipyretics are even less suitable than in typhoid, as the tendency to heart-weakness is often more pronounced. As a rule, the patients require from the outset a supporting treatment. The bowels may be kept open by mild aperients and enemas. The special nervous symptoms and the pulmonary symptoms should be dealt with as in typhoid fever. In epidemics, when the conditions of the climate are suitable, the patients are best treated in tents in the open air.

VIII. DENGUE

Definition.—An acute disease of tropical and subtropical regions, characterized by febrile paroxysms, pains in the joints and muscles, an initial erythematous and a terminal polymorphous eruption. It is known as *break-bone* fever from the atrocious character of the pain, and *dandy fever* from the stiff, dandified gait. The word dengue is supposed to be derived from a Spanish, or possibly Hindostanee, equivalent of the word dandy.

History and Geographical Distribution.—The disease was first recognized in 1779 in Cairo and in Java, where Bylon described the outbreak in Batavia. There have been widespread epidemics in India and China. The description by Benjamin Rush of the epidemic in Philadelphia in 1780 is one of the first and best accounts of the disease. Between 1824 and 1828 it was prevalent at intervals in India and in the southern states. S. H. Dickson gives a graphic description of the disease as it appeared in Charleston in 1828. Since that date there have been widespread epidemics in tropical countries and in North America along the Gulf States. There were 30,000 cases in Galveston in 1922. None of the recent epidemics extended into the northern states, but in 1888 it prevailed as far north as Virginia.

Etiology.—The rapidity of diffusion and the pandemic character are two important features of dengue. There is no disease, not even influenza, which attacks so large a proportion of the population. The specific cause is a filterable virus present in the blood for at least the first three days of the attack. The disease is transmitted by a mosquito, *Aedes aegypti*. Biting experiments are successful (after eleven days from infection of the mosquito) and it is transmitted by injecting the blood subcutaneously. The virus is present in the whole blood, the serum and the fluid part of citrated blood.

As the disease is rarely fatal, no observations have been made upon its pathological anatomy.

Symptoms.—The period of incubation is from three to seven days, during which the patient feels well. The attack sets in suddenly with headache, chilly

feelings, and intense aching pains in the joints and muscles. The temperature rises gradually, and may reach 106° or 107° . The pulse is rapid, and there are the other phenomena associated with acute fever—loss of appetite, coated tongue, slight nocturnal delirium, and concentrated urine. The face has a suffused, bloated appearance, the eyes are injected and painful, and the mucous membranes are flushed. There is a congested erythematous state of the skin. Rush's description of the pains is worth quoting, as in it the epithet break-bone occurs in the literature for the first time. "The pains which accompanied this fever were exquisitely severe in the head, back, and limbs, the pains in the head were sometimes in the back parts of it, and at other times they occupied only the eyeballs. In some people the pains were so acute in their backs and hips that they could not lie in bed. In others the pains affected the neck and arms, so as to produce in one instance a difficulty of moving the fingers of the right hand. They all complained more or less of a soreness in the seats of these pains, particularly when they occupied the head and eyeballs. A few complained of their flesh being sore to the touch in every part of the body. From these circumstances the disease was sometimes believed to be a rheumatism, but its more general name among all classes of people was the break-bone fever." The large and small joints are affected, sometimes in succession, and become swollen, red, and painful. In some cases cutaneous hyperæsthesia has been noted. Hæmorrhage from the mucous membranes was noted by Rush, and black vomit has been described.

The fever gradually reaches its maximum by the third or fourth day; the patient then enters upon the apyretic period, which may last from two to four days, and in which he feels prostrated and stiff. A second paroxysm of fever then occurs, and the pains return. In a large number of cases an eruption is common, which, judging from the description, has nothing distinctive, being sometimes macular, like that of measles, sometimes diffuse and scarlatiniform, or papular, or lichen-like. In other instances the rash has been described as urticarial, or even vesicular. The rash may persist for a month after the symptoms have disappeared. Certain writers describe inflammation and hyperæmia of the mucous membrane of the nose, mouth and pharynx. Enlargement of the lymph-glands is not uncommon, and may persist for weeks after the attack. There is a normal or low leucocyte count with a relative lymphocytosis. Convalescence is often protracted, and there is marked mental and physical prostration. The pains in the joints or muscles, sometimes very local, may persist for weeks. Rush refers to the former, stating that a young lady after recovery said it should be called break-heart, not break-bone, fever. The average duration of a moderate attack is from seven to eight days. Dengue is very seldom fatal. Dickson saw three deaths in the Charleston epidemic.

Complications are rare. Insomnia and occasionally delirium have been observed, and convulsions in children. Atrophy of the muscles may occur after the attack. A relapse may occur even as late as two weeks.

Diagnosis.—The diagnosis of the disease, prevailing as it does in epidemic form and attacking all classes indiscriminately, rarely offers any special difficulty. Isolated cases might be mistaken at first for rheumatic fever. The seven-day fever of East Indian ports is believed to be dengue. It is a sporadic fever of the hot weather, attacking a large proportion of Europeans within

the first year or two of their arrival. It is characterized by early and severe pains in the back and limbs, and a fever of six to seven days' duration. Very careful study may be required to distinguish dengue from yellow fever and influenza.

Treatment.—The patients should be protected from mosquitoes during the febrile period. The treatment is entirely symptomatic. Hydrotherapy may be employed to reduce the fever. The salicylates or antipyrin may be tried for the pains, which usually, however, require opium. During convalescence iodide of potassium is recommended for the arthritic pains, and tonics are indicated.

IX. HYDROPHOBIA

(*Lyssa; Rabies*)

Definition.—An acute disease of warm-blooded animals, dependent upon a filterable virus which is communicated by inoculation to man.

Distribution.—Rabies is very variously distributed. In Russia it is common. In North Germany it is relatively rare, owing to the wise provision that all dogs must be muzzled. In France it is much more common. In England the muzzling order has been followed by a complete disappearance of the disease and there were no deaths from 1912-1928. In the decennium ending with 1890 the deaths averaged 29 annually (Tatham). In the United States there has been a yearly average of 64 deaths in the registration area from 1911-1920 and 83 deaths in 1925.

Etiology.—Dogs are especially liable to the disease. It also occurs in the wolf, fox, skunk, cat, horse and cow. Most animals are susceptible; and it is communicable by inoculation to the rabbit and pig. The disease is propagated chiefly by the dog. The nature of the virus is as yet unknown. It is contained chiefly in the nervous system and in some of the secretions, particularly in the saliva. Bartarelli has shown that the virus reaches the dog's salivary glands by way of the nerves and not through the blood-vessels.

A variable time elapses between the introduction of the virus and the appearance of the symptoms. Horsley stated that this depends upon the following factors: "(a) Age. The incubation is shorter in children than in adults. For obvious reasons the former are more frequently attacked. (b) Part infected. The rapidity of onset of the symptoms is greatly determined by the part of the body which may happen to have been bitten. Wounds about the face and head are especially dangerous; next in order in degrees of mortality come bites on the hands, then injuries on the other parts of the body. This relative order is, no doubt, greatly dependent upon the fact that the face, head, and hands are usually naked, while the other parts are clothed; it would also appear to depend somewhat upon the richness in nerves of the part. (c) The extent and severity of the wound. Puncture wounds are the most dangerous; the lacerations are fatal in proportion to the extent of the surface afforded for absorption of the virus. (d) The animal conveying the infection. In order of decreasing severity come: first, the wolf; second, the cat; third, the dog; and fourth, other animals." Only a limited number of those bitten by rabid dogs become affected by the disease; according to Hors-

ley, not more than 15 per cent. On the other hand, the death-rate of those persons bitten by wolves is higher, not less than 40 per cent. Babes gives the mortality as from 60 to 80 per cent.

The *incubation* period in man is extremely variable. The average is from six weeks to two months. In a few cases it has been under two weeks. It may be prolonged to three months. It is stated that the incubation may be prolonged for a year or even two years, but this has not been definitely settled.

Morbid Anatomy.—The important lesions consist in the accumulation of leucocytes around the blood-vessels and the nerve-cells, particularly the motor ganglion cells, of the central nervous system (rabic tubercles of Babes). Especial importance in the rapid diagnosis of rabies is attached by van Gehuchten and Nelis to the accumulation of lymphoid and endothelioid cells around nerve-cells of the sympathetic and cerebro-spinal ganglia. Negri described in the central nervous system irregular bodies varying from 4 to 10 microns in size, widespread, frequently in the cells of the cerebellum, cerebral cortex and pons, and in the spinal cord. They furnish a rapid and trustworthy means of diagnosis. The virus is not present in the liver, spleen, or kidneys, but is abundant in the spinal cord, brain, and peripheral nerves. In the spinal fluid the globulin is increased and often the cells, polynuclear or mononuclear.

Symptoms.—Three stages of the disease are recognized:

(a) **PREMONITORY STAGE**, in which there may be irritation about the bite, pain, or numbness. The patient is depressed and melancholy; and complains of headache and loss of appetite. He is irritable and sleepless, and has a sense of impending danger. There is often greatly increased sensibility. A bright light or a loud voice is distressing. The larynx may be injected, the voice becoming husky, and the first symptoms of difficulty in swallowing are experienced. There is a slight rise in the temperature and pulse.

(b) **STAGE OF EXCITEMENT.**—This is characterized by great excitability and restlessness, and an extreme degree of hyperæsthesia. "Any afferent stimulant—i. e., a sound or a draught of air, or the mere association of a verbal suggestion—will cause a violent reflex spasm. In man this symptom constitutes the most distressing feature of the malady. The spasms, which affect particularly the muscles of the larynx and mouth, are exceedingly painful and are accompanied by an intense sense of dyspnœa, even when the glottis is widely opened or tracheotomy has been performed" (Horsley). Any attempt to swallow is followed by an intensely painful spasm of the muscles of deglutition and respiration. These spasmodic attacks may be associated with maniacal symptoms. In the intervals the patient is quiet and the mind unclouded. The temperature in this stage is usually elevated and may reach from 100° to 103°. In some instances the disease is afebrile. The patient rarely attempts to injure his attendants, and in the intense spasms may be particularly anxious to avoid hurting any one. There are, however, occasional fits of furious mania, and the patient may, in the contractions of the muscles of the larynx and pharynx, give utterance to odd sounds. This stage lasts from a day and a half to three days and gradually passes into the—

(c) **PARALYTIC STAGE.**—In rodents the preliminary and furious stages are absent, as a rule, and the paralytic stage may be marked from the outset—the so-called dumb rabies. This stage rarely lasts longer than from six to eighteen hours. The patient then becomes quiet; the spasms no longer occur;

unconsciousness gradually supervenes; the heart's action becomes more and more enfeebled, and death occurs by syncope.

Diagnosis.—In man this offers no special difficulties. *Tetanus* is distinguished by trismus, the presence of persistent and not intermittent muscle spasm and the absence of special involvement of the muscles of deglutition and respiration. *Lyssophobia* should not cause difficulty if a careful examination is made. It is advisable, in cases with any doubts, as soon as possible after the injury, to secure the brain of the supposed rabid animal for examination. The recognition of the Negri bodies in smears of brain substance enables the diagnosis to be made promptly.

Prophylaxis.—This is of the greatest importance, and by a systematic muzzling of dogs the disease can be practically eradicated. In case of a bite from a suspicious animal, bleeding should be encouraged, the wound freely opened and washed with bichloride of mercury solution (1 to 1,000). Thorough cauterization should be done as soon as possible, for which pure phenol or nitric acid should be used, being applied to every part of the wound. The wound is washed with a saturated solution of bicarbonate of soda and then with alcohol.

PREVENTIVE INOCULATION.—Pasteur found that the virus, when propagated through a series of rabbits, increases in its virulence; so that whereas subdural inoculation of the brain of a mad dog takes from fifteen to twenty days to produce the disease, in successive inoculation in a series of rabbits the incubation period is gradually reduced to seven days (*virus fixe*). The spinal cords of these rabbits contain the virus in great intensity, but when preserved in dry air this gradually diminishes. If dogs are inoculated from cords preserved for from twelve to fifteen days, and then from cords preserved for a shorter period, i. e., with a progressively stronger virus, they gradually acquire immunity against the disease. Relying upon these experiments, Pasteur began inoculations in the human subject, using, on successive days, material from cords in which the virus was of varying degrees of intensity. In a few cases neuritis follows the treatment.

In 1910, 410 patients were treated at the Pasteur Institute of Paris without a death; in 1908 and 1909, 991 cases with 2 deaths. There has been a progressive decline in the number of cases and in the mortality.

Treatment.—When once established the disease is hopelessly incurable. No measures have been found of the slightest avail, consequently the treatment must be palliative. The patient should be kept as quiet as possible in a darkened room. To allay the spasm, chloroform may be administered and morphia given hypodermically. It is best to use these remedies from the outset, and not temporize with chloral, bromide of potassium, and other less potent drugs. By the local application of cocaine, the sensitiveness of the throat may be diminished sufficiently to enable the patient to take liquid nourishment. Sometimes he can swallow readily. Fluid can be given by the bowel.

Pseudo-hydrophobia (*Lyssophobia*).—This may closely resemble hydrophobia, but is nothing more than a neurotic or hysterical manifestation. A nervous person bitten by a dog, either rabid or supposed to be rabid, has within a few months, or even later, symptoms somewhat resembling the true disease. He is irritable and depressed, and constantly declares his condition to be seri-

ous and that he will inevitably become mad. He may have paroxysms in which he says he is unable to drink, grasps at his throat, and becomes emotional. The temperature is not elevated and the disease does not progress. It lasts much longer than the true rabies, and is amenable to treatment. It is not improbable that a majority of the cases of alleged recovery in this disease have been of this hysterical form. Certain cases of acute bulbar paralysis may resemble hydrophobia, and, as already mentioned, there is a form of tetanus with hydrophobic symptoms.

X. RHEUMATIC FEVER

Definition.—An acute infection, probably caused by various strains of streptococci, and characterized by arthritis, myocarditis, and a marked tendency to inflammation of the endocardium of the valves of the heart.

Etiology.—**DISTRIBUTION AND PREVALENCE.**—It prevails in temperate and humid climates, and is apparently rare in the tropics. In England and Wales in 1928 there were 1,500 deaths from the disease and 2,766 deaths in the U. S. registration area for 1925. The disease prevails more in the northern latitudes. In the Montreal General Hospital there were, for the twelve years ending 1903, 2 deaths in 482 cases among 12,044 admissions; at the Royal Victoria Hospital, Montreal, for ten years ending 1903, 3 deaths in 285 cases among 9,286 admissions (John McCrae). At the Johns Hopkins Hospital for the fifteen years ending 1904 there were 360 admissions (330 patients) and 9 deaths. The general impression is that the disease prevails more in the British Isles than elsewhere; but the returns are imperfect (this holds good everywhere).

SEASON.—In London the cases reach the maximum in the months of September and October. Bell's statistics of 456 cases in Montreal show that the largest number was admitted in February, March, and April. The same is true in Baltimore; 55 per cent. of the cases were admitted in the first four months of the year. The disease prevails most in dry years or a succession of such, and is specially prevalent when the subsoil water is abnormally low and the temperature of the earth high (Newsholme).

AGE.—Young adults are frequently affected, but the disease is common in children. In England the incidence in children is very high. In 2,556 examined by Langmead, 133 were definitely rheumatic and in all but 18 the heart was involved. In 43 per cent. of these cases there was some abnormality of the tonsils or pharyngeal mucosa. Sucklings are rarely attacked. Milton Miller analyzed 19 undoubted cases. They have to be distinguished from a totally different affection, the pyogenic arthritis of infants. Of 456 cases admitted to the Montreal General Hospital there were, under fifteen years, 4.38 per cent.; from fifteen to twenty-five years, 48.68 per cent.; from twenty-five to thirty-five years, 25.87 per cent.; from thirty-five to forty-five years, 13.6 per cent.; above forty-five years, 7.4 per cent. Of our 360 admissions, 110 were in the third decade and 65 per cent. below the thirtieth year of age. Ten per cent. of the cases had the first attack in the first decade. These figures do not give the ratio of cases in children, in whom the milder types of arthritis are very common.

SEX.—If all ages are taken, males are affected oftener than females. Of our patients, 239 were males, 91 females. In the Collective Investigation Report there were 375 males and 279 females. Up to the age of twenty, however, females predominate. Between the ages of ten and fifteen girls are more prone to the disease.

HEREDITY.—It is a deeply grounded belief that this is a family disease, but the evidence is imperfect. The not rare occurrence in several members of the same family is used by those who believe in the infectious origin as an argument in favor of its being a house disease.

CHILL.—Exposure to cold, a wetting, and a sudden change of temperature are among the factors in determining the onset of an attack, but they were present in only 12 per cent. of our cases.

Not only does an attack not confer immunity, but, as in pneumonia, predisposes the subject to further manifestations of the disease. One view is that a condition of allergy is established.

The Nature of Rheumatic Fever.—The view is gaining ground that the manifestations of the disease represent a condition of hypersensitiveness to various forms of streptococci. With this conception there are points of resemblance to tuberculosis and syphilis in the allergic response and in the fact that the lesion is a granuloma. There is an initial lesion with more serious manifestations occurring elsewhere in the body. The initial lesion may be in the tonsils with resulting sensitization and subsequent attacks may be due to fresh infection or to areas of chronic infection (tonsils, sinuses). Organisms are recovered from patients with the disease only in a small proportion of cases. The organisms found are usually non-hemolytic streptococci with no immunological relationship. This suggests that rheumatic fever may represent a response to a number of organisms and not be caused by a specific organism. The work of Swift is very suggestive of this. Patients once infected may react to filtrates of many types of streptococci. This hypersensitiveness may be due to two products, (1) a neutralizable toxin and (2) some non-neutralizable substance. The disease can not be reproduced in animals but inoculations in rabbits with the organisms obtained show various allergic reactions. In the human infection, the lesions are exudative at first and later proliferative. A hypersensitive state once established, a chronic infection, or repeated slight infections, may serve to prolong it and an acute infection may precipitate another acute attack. Long after an acute attack there may be active lesions in the body.

The tonsils are culture centres for many organisms, particularly of the streptococcus type. The association of rheumatic fever and arthritic affections generally with infected tonsils is a prevailing view, but it is an old story insisted on by Lasague and other French writers years ago. Some cases of rheumatic fever begin with tonsillitis. There is considerable evidence against the view that it is simply a pyogenic infection. Salicylates have no effect on the ordinary streptococcus infections, and the clinical course in the streptococcus arthritis is very different; rheumatic joints never suppurate. The endocarditis with a pyogenic streptococcus infection is of a very different character from that of rheumatic fever.

Morbid Anatomy.—The affected joints show hyperæmia and swelling of the synovial membranes and of the ligamentous tissues. The fluid in the

joint is turbid, albuminous, and contains leucocytes and a few fibrin flakes. Rheumatic fever rarely proves fatal, except with complications, such as pericarditis, endocarditis, myocarditis, pleurisy, or pneumonia. The changes in the myocardium are regarded as characteristic by many workers. The sub-miliary nodules, described by Aschoff, are most often in the wall of the left ventricle, but may be in the auricle, aorta and elsewhere. The lesions in the aorta may occur in all the coats and the Aschoff bodies have been found in the adventitia. Fibrosis and calcification may occur. There are fan-shaped collections of giant cells, perivascular fibrous nodules, and infiltration of small cells into the surrounding tissue. Klotz has drawn attention to the frequency of arterial lesions, especially in the aorta. Changes in the coronary arteries, an inflammatory fibrosis, are common.

Symptoms.—As a rule, the disease sets in abruptly, but it may be preceded by irregular pains in the joints, slight malaise, sore throat, and particularly by tonsillitis. A definite rigor is uncommon; more often there is slight chilliness. The fever rises quickly, and with it one or more of the joints become painful. Within twenty-four hours from the onset the disease is fully manifest. The temperature range is from 102° to 104°. The pulse is frequent, soft, and usually above 100. The tongue is moist and covered with a white fur. There are the ordinary symptoms associated with an acute fever, such as loss of appetite, thirst, constipation, and scanty, highly acid urine. In a majority of the cases there are profuse, very acid sweats, of a peculiar sour odor. Sudamina and miliary vesicles are abundant, the latter usually surrounded by a minute ring of hyperæmia. The mind is clear, except with hyperpyrexia. The affected joints are painful to move, soon become swollen and hot, and present a reddish flush. The order of frequency of involvement of the joints in our series was knee, ankle, shoulder, wrist, elbow, hip, hand, foot. The joints are not attacked together, but successively. For example, if the knee is first affected, the redness may disappear from it as the wrists become involved. The disease is seldom limited to a single articulation. The amount of swelling is variable. Extensive effusion into a joint is rare, and much of the enlargement is due to the infiltration of the periarticular tissues with serum. The swelling may be limited to the joint proper, but in the wrists and ankles it sometimes involves the sheaths of the tendons. Corresponding joints are often affected. In attacks of great severity every one of the larger joints may be involved. The vertebral, sterno-clavicular, and phalangeal articulations are not often involved. Perhaps no disease is more painful; the inability to change the posture without agonizing pain, the drenching sweats, the prostration and helplessness, combine to make it a most distressing affection. A special feature is the tendency of the inflammation to subside in one joint while increasing in another.

The temperature range in an ordinary attack is between 102° and 104° F. In only 18 of our cases did the temperature rise above 104° F. In 100 it reached 103° F. or over. It is peculiarly irregular, with marked remissions and exacerbations, and defervescence is usually gradual. The profuse sweats materially influence the temperature curve. If a two-hourly chart is made and observations upon the sweats are noted, the remissions will usually be found coincident with them.

The blood is profoundly altered and there is no acute febrile disease in

which an anæmia occurs with greater rapidity. The average leucocyte count in our cases was about 12,000 per c. mm. Epistaxis is not uncommon.

With the high fever a murmur may often be heard at the apex region. Endocarditis is also a common cause of an apex *bruit*. The heart should be carefully examined at the first visit and subsequently each day.

The urine is, as a rule, reduced in amount, of high density and high color. It is very acid, and, on cooling, deposits urates. The chlorides may be greatly diminished or even absent. Formic acid is present (Walker). Febrile albuminuria is not uncommon. Hæmaturia occurs occasionally.

Subacute rheumatic fever represents a milder form of the disease, in which all the symptoms are less pronounced. The fever rarely rises above 101° F.; fewer joints are involved; and the arthritis is less intense. The cases may drag on for weeks or months. It should not be forgotten that mild or subacute forms may be associated with endocarditis or pericarditis.

The influence of age on the manifestations is marked. While the usual description applies to the disease as seen in adults, in young children there may not be any pronounced arthritis or any arthritis at all, and the discovery of endocarditis often suggests the diagnosis. Endocarditis and myocarditis are the prominent features in children as arthritis is in adults.

Complications.—These are important and serious.

(a) HYPERPYREXIA.—The temperature may rise rapidly a few days after the onset, and be associated with delirium. It is most apt to occur during the second week. Delirium may precede or follow its onset. In our series there was no instance of hyperpyrexia; it seems rare in the United States.

(b) CARDIAC AFFECTIONS.—(1) Endocarditis occurs in a considerable percentage of all cases. Of 889 cases, 494 had signs of old or recent endocarditis (Church). The liability to endocarditis diminishes as age advances. Its incidence in our cases was more than double in patients who had their first attack before the age of twenty years, compared with those with the first attack after twenty years of age. It increases directly with the number of attacks. Of 116 cases, in the first attack 58.1 per cent. had endocarditis, 63 per cent. in the second attack, and 71 per cent. in the third attack (Stephen Mackenzie). Thirty-five per cent. of our cases showed organic valve lesions; in 96 per cent. the mitral was involved, in 27 per cent. the aortic, and in 23 per cent. the lesions were combined. The mitral segments are most frequently involved and the affection is usually of the simple, verrucose variety. Ulcerative endocarditis is very rare. The valvulitis in itself is rarely dangerous, producing few symptoms, and often overlooked. Unhappily, though the valve at the time may not be seriously damaged, the inflammation starts changes which lead to sclerosis of the segments, and so to chronic valvular disease. Venous thrombosis is an occasional complication.

(2) Pericarditis may occur independently of or with endocarditis. It may be simple fibrinous, sero-fibrinous, or in children purulent. It was present in 20 cases of our series—6 per cent.—in only four of which did effusion occur. The physical signs are very characteristic. The condition is described under its appropriate section. A peculiar form of delirium may accompany rheumatic pericarditis.

(3) Myocarditis is probably always present in some degree and is especially marked in connection with endopericardial changes. As Sturges insisted,

the term *carditis* is applicable to many cases. The anatomical condition is a degeneration of the heart-muscle, which leads to weakening of the walls and dilatation. There is dilatation of the heart in the majority of cases during the acute period and practically always in children. The rate is increased, there is often a diffuse impulse, the dulness is increased, especially to the right, the first sound may be soft and murmurish or completely replaced by a murmur. It may be difficult for some weeks to make the diagnosis from endocarditis.

Many *electrocardiographic* changes are found (in over 90 per cent. of cases) such as extra systoles, various degrees of auriculo-ventricular block, auricular paroxysmal tachycardia and changes in various waves. These are often transient. Delayed auriculo-ventricular conduction is frequent and is an important diagnostic point of rheumatic fever in the absence of any other cause for it.

(c) *AORTITIS*.—This is especially common in children and particularly with aortic endocarditis. The enlargement of the aorta may be marked. In some cases the acute condition results in permanent dilatation. *Arteritis* should be carefully looked for; there may be marked tenderness on pressure over the artery.

(d) *PULMONARY AFFECTIONS*.—Pneumonia and pleurisy occurred in 9.94 per cent. of 3,433 cases (Stephen Mackenzie). They frequently accompany the cases of endo-pericarditis. According to Howard's analysis of a large number of cases, there were pulmonary complications in only 10.5 per cent. of cases of rheumatic endocarditis; in 58 per cent. of cases of pericarditis; and in 71 per cent. of the cases of endo-pericarditis.

(e) *NERVOUS COMPLICATIONS*.—They may be grouped as follows: (i) *Cerebral*, characterized by (a) *delirium*, associated with the hyperpyrexia or the toxæmia. It may be excited by the sodium salicylate. It was present in only 5 of our 360 cases, and in 4 of these we thought the salicylates at fault. A peculiar delirium occurs in connection with rheumatic pericarditis. (β) *Coma* may occur without preliminary delirium or convulsions and prove rapidly fatal. Certain cases occur with hyperpyrexia, but others are evidently uræmic. (γ) *Convulsions* are less common, though they may precede the coma. (ii) *Chorea*. The relations of this disease and rheumatic fever will be subsequently discussed. In only 88 of 554 cases from the Infirmary for Diseases of the Nervous System, Philadelphia, were chorea and rheumatism associated. It is most apt to develop in the slighter attacks in childhood. (iii) *Meningitis* is extremely rare, though undoubtedly it does occur. (iv) *Polyneuritis* has been described and may follow hyperpyrexia. In one case free venesection saved the patient's life. After many months the patient recovered, but with ataxia.

(f) *CUTANEOUS AFFECTIONS*.—Sweat-vesicles are extremely common and a red miliary rash may also develop. Scarlatiniform eruptions are occasionally seen. Depressions on the nails may follow rheumatic fever or chorea. Purpura, with or without urticaria, and various forms of erythema may occur. It is doubtful whether the cases of extensive purpura with urticaria and arthritis—*peliosis rheumatica*—belong to rheumatic fever.

(g) *RHEUMATIC NODULES*.—These curious structures, described originally by Meynet, occur in the form of small subcutaneous nodules. Barlow and

Warner, in England, and T. B. Fitcher, in the United States, have paid special attention to their varieties and importance. They vary in size from a small shot to a large pea, and are most numerous on the fingers, hands, and wrists. They also occur about the elbows, knees, the spines of the vertebrae, and the scapulae. They are not often tender. They are more common after the decline of the fever and in the children with endocarditis. In only 5 of our patients were they noted during the acute attack. The nodules may grow with great rapidity and usually last for weeks or months. They are more common in children than in adults, and in the former their presence may be regarded as an indication of rheumatic fever. Subcutaneous nodules occur also in migraine, gout, and arthritis deformans. Histologically they are made up of round and spindle-shaped cells and may contain Aschoff bodies. They suggest a proliferative response to the infection.

(h) Swelling or tenderness of the thyroid gland may be present.

Course.—This is extremely variable. Rheumatic fever is, as Austin Flint first showed, self-limited, but this does not mean that it follows a regular course. A usual average of symptoms in uncomplicated cases is from two to three weeks, but with endocarditis the illness may last for months. Relapse and recrudescence are common and the period of rest should be prolonged. The frequency of myocarditis is an additional reason for caution. In patients with previous endocarditis the course is usually protracted.

Prognosis.—Rheumatic fever is the most serious of all diseases with a low death-rate. The mortality is rarely above 2 or 3 per cent. Only 9 of our 330 patients died, 2.7 per cent., all with endocarditis and 6 with pericarditis.

Sudden death in rheumatic fever is due most frequently to myocarditis. Herringham has reported a case in which on the fourteenth day there was fatty degeneration and acute inflammation of the myocardium. In a few rare cases it results from embolism. Symptoms of depression sometimes follow excessive doses of sodium salicylate.

Diagnosis.—Practically, the recognition of rheumatic fever is usually easy; but there are several affections which, in some particulars, closely resemble it.

(a) **MULTIPLE SECONDARY ARTHRITIS.**—Under this term may be embraced the forms of arthritis which occur with or follow tonsillitis, scarlet fever, dysentery, cerebro-spinal meningitis, etc. The associated features usually make the diagnosis clear.

(b) **SEPTIC ARTHRITIS**, which occurs in the course of septicopyæmia from any cause, and particularly in puerperal fever. No hard and fast line can be drawn between these and the cases in the first group: but the inflammation often passes on to suppuration and there is more or less destruction of the joints. The conditions under which the arthritis occurs give a clue to the nature of the case. Under this section may be mentioned:

(1) Acute necrosis or acute osteomyelitis may be mistaken for rheumatic fever. Sometimes it is multiple. The greater intensity of the local symptoms, the involvement of the epiphyses rather than the joints, and the more serious constitutional disturbances are points to be considered. The condition is unfortunately often mistaken for acute arthritis, and, as the treatment is essentially surgical, the error may cost the life of the patient. Rheumatic fever is extremely rare in very young children.

(2) *The acute arthritis of infants* is usually confined to one joint (the hip or knee), the effusion in which rapidly becomes purulent. The affection is most common in sucklings and undoubtedly pyæmic in character. It may also occur with the gonorrhœal ophthalmia or vaginitis of the new-born.

(c) *GONOCOCCUS ARTHRITIS*.—This may give difficulty at the onset, but there is not the rapid shifting from joint to joint and there is usually some thickening about the most affected joints in a short time. A careful search for gonococci is important and the complement fixation test may aid.

(d) *GOUT*.—While the localization in a single, usually a small, joint, the age, the history, and the mode of onset enable us to recognize acute gout, there are everywhere cases of acute arthritis, called rheumatic fever, which are in reality gout. The involvement of several of the larger joints is not so infrequent in gout, and unless tophi are present or bursitis occurs, the diagnosis may be difficult. The dusky red color of the skin over the affected joints, severe pain when the joint is at rest, and less fever relatively than the intensity of the arthritis, are helpful points in gout.

(e) *ACUTE ARTHRITIS DEFORMANS*.—This may easily be mistaken for rheumatic fever. It may come on with fever and multiple arthritis, and for weeks there may be no suspicion of the true nature of the disease. Gradually the fever subsides, but the periarticular thickening persists. As a rule, in the acute febrile cases the involvement of the smaller joints, the persistence and the changes in the articulations suggest arthritis deformans.

In *children* the diagnosis of rheumatic fever may be very difficult, as arthritis may be slight or entirely absent. The possibility of rheumatic fever should be considered in all febrile attacks in children for which no definite cause can be found. Special care should be given to the examination of the heart, particularly for any signs of dilatation or endocarditis.

Treatment.—The main object should be to bring the patient through the attack with an undamaged heart or with as little injury as possible. The first essential is complete rest, which should be begun at once and insisted upon for as long as is necessary. This is especially important for children. The duration of rest has to be decided for each patient. Special thought should be given to the myocardium. Until it is restored to the best possible condition rest is indicated, frequently for months. Convalescence should never be hurried and the safe rule is to increase exertion very slowly—if in doubt, delay. The bed should have a smooth, soft, yet elastic, mattress. The patient should wear a flannel nightgown, which may be opened all the way down the front and slit along the outer margin of the sleeves. Three or four of these should be made, so as to facilitate the frequent changes required after the sweats. He may wear also a light flannel cape about the shoulders. He should sleep in blankets, not in sheets, so as to reduce the chance of being chilled.

Milk is the most suitable diet and may be diluted with alkaline mineral waters. Fruit juices, lemonade and oatmeal or barley water should be freely given. The thirst should be fully satisfied. There is no objection to soups if the milk is not well borne. As convalescence is established a fuller diet may be allowed, but meat should be used sparingly.

Local treatment is usually necessary. It often suffices to wrap the affected joints in cotton. If the pain is severe, hot cloths may be applied, saturated with Fuller's lotion (carbonate of soda, 6 drams, 24 gm.; laudanum, 1 oz., 30

c. c.; glycerine, 2 oz., 60 c. c.; and water, 9 oz., 270 c. c.) or the lead and opium lotion. Oil of wintergreen is useful, the joint being gently rubbed with it or small amounts sprinkled over flannel, which is then applied. Chloroform liniment is also a good application. Fixation of the joints is of great service in allaying the pain. Splints, padded and bandaged with moderate firmness, will often give comfort. Cold compresses are sometimes useful. The application of blisters above and below the joint often relieves the pain but this is not to be compared with the light application of the cautery. If there is much effusion, aspiration of the joint is useful.

The drug treatment is still far from satisfactory, though the introduction of the salicyl compounds has been a great boon.

SALICYLATES.—Introduced by MacLagan in 1876 in the form of salicin, the salicylates in some cases may be regarded as having an action which is almost specific. They relieve pain, often seem to shorten the course, and lessen the chances of relapse. Certainly the occurrence of hyperpyrexia and pericarditis seems to have greatly decreased since their use. There is no proof that they influence endocarditis unless by shortening the febrile period its chance of development is lessened. The best preparation is sodium salicylate, usually given with sodium bicarbonate. The drug should be given in amounts of 120 grains (8 gm.) in the twenty-four hours as an average. An excellent plan is to give a large dose (60 to 90 grains, 4 to 6 gm.) by rectum once a day, reducing the dose by mouth if this is done. If administration by mouth causes gastric disturbance, the drug can be given by rectum. In severe cases it is well to give 90 gr. (6 gm.) by rectum at once and an equal amount by mouth in the first twenty-four hours. Children as a rule stand the drug well and depressing effects are rarely seen. The natural has no advantage over the synthetic product. Of other salicylate preparations acetyl-salicylic acid may be given, but none is equal to the sodium salt. After the fever has lessened and the pain decreased the dose can be gradually reduced. It is wise not to discontinue the drug until the danger of relapse is over. The giving of salicylate intravenously is not advised.

ALKALINE TREATMENT.—The urine should be rendered alkaline as soon as possible. Potassium acetate and citrate in doses of 15 grains (1 gm.) each are given every three hours until the urine is alkaline and then often enough to keep it so. Potassium or sodium bicarbonate may be given with the sodium salicylate.

Cinchophen and its variations are useful. Doses of 15 to 30 grains (1-2 gm.) may be given every two or three hours for three doses and then every four hours, with reduction in the amount if the symptoms are relieved.

A popular belief attributes efficacy to bee-stings in all sorts of "rheumatism," and a formic-acid treatment has been introduced. A 2½ per cent. solution is injected in the neighborhood of the painful joints. Ainley Walker collected (B. M. J., October 10, 1908) an interesting literature on the subject.

To allay the pain opium may be given in the form of Dover's powder, or morphia hypodermically. The coal tar products are sometimes useful for the purpose. During convalescence iron is indicated in full doses. Of the complications, hyperpyrexia should be treated by the bath or the cold pack. The treatment of endocarditis and pericarditis and the pulmonary complications

will be considered under their respective sections. In all the cardiac complications the importance of prolonged rest must be remembered.

To prevent and arrest endocarditis Caton urged the use of a series of small blisters along the course of the third, fourth, fifth, and sixth intercostal nerves of the left side, applied one at a time and repeated at different points. Potassium or sodium iodide is given in addition to the salicylates.

TONSILS.—With disease of these and the possibility that they are the portals of entry for the infective agent, the question arises as to their removal. In patients with diseased tonsils in whom rheumatic fever has occurred removal is advisable and should be complete. In patients with endocarditis and fever this can be done without risk in many patients. Sodium salicylate should be given for some days before the operation, and afterwards.

XI. ERYTHEMA NODOSUM

This cannot be regarded as a specific disease and its exact position in any classification is not settled. Many believe that it has a close relationship to rheumatic fever, while some regard it as a manifestation of tuberculosis. Probably it is a condition which may result from various causes. There is good evidence that it is due to a streptococcal infection in some cases. It occurs usually below the age of twenty years and much more often in females than in males.

Clinical Features.—The onset may be with malaise, sore throat, more or less general pains and slight fever. The last is rarely high but may persist for some time. The local lesions consist of round or oval areas, slightly raised, dusky red in color, tender and rarely more than two inches in diameter. There may be some œdema of the surrounding tissue. They are usually bilateral and occur most often on the legs, especially over the tibia, but may be on the arms or over the scapula. They may come out in crops and the total number is variable. Suppuration may be suspected but does not occur. The duration of each node is about ten days and discoloration is left behind. The attack may last for two or three weeks. The *diagnosis is not* difficult but they have been mistaken for syphilitic nodes. By the laity they may be mistaken for bruises and unjust charges of cruelty have resulted.

Treatment.—The patient should be in bed until the nodes have disappeared. The salicylates sometimes relieve the pain and should be tried. Local sedative applications to the lesions are useful. Careful search should be made for any focus of infection and, in view of the occasional association with tuberculosis, for any lesion of that disease.

XII. ACUTE TONSILLITIS

Definition.—An acute infection, sporadic or epidemic, involving the structures of the tonsillar ring, usually due to organisms of the streptococcus class.

Etiology.—Acute tonsillitis occurs in sporadic and epidemic forms. The *sporadic* variety occurs in young persons particularly. Infants are rarely attacked. Chronic enlargement of the lymphatic structures of the throat is a

predisposing cause. Exposure to cold and wet may predispose to an attack. It is directly communicated from one to another. It may be followed by endocarditis, erythema nodosum, chorea, and acute nephritis. Felty and Hodges, from an extensive study, regard the causal organism as the *Streptococcus hæmolyticus* of the beta type. While not absolutely identical in all cases the organisms are intimately related forms of beta-hæmolytic streptococci. With this view the disease is to be regarded as a specific infection rather than as a syndrome which may be caused by various organisms. In some cases the predominating organism seems to be the pneumococcus. The source of infection is usually a carrier of the organism and the conditions of indoor life in cold seasons naturally favor infection.

Epidemic tonsillitis is not infrequent, the cases increasing in the community to epidemic proportions. As a rule it is impossible to trace it to any special cause. There are remarkable localized outbreaks, sometimes in institutions, which have been traced to milk infection. The one in Boston in 1911 was exceptionally severe, involving more than 1,000 persons, and the connection with the milk from one dairy seems to have been proved.

Morbid Anatomy.—The lacunæ of the tonsils become filled with exudation products, which form cheesy-looking masses, projecting from the orifices of the crypts. Not infrequently the exudations from contiguous lacunæ coalesce. The intervening mucosa is usually swollen, deep red in color, and may present herpetic vesicles, or, in some instances, even membranous exudation, in which case it may be difficult to distinguish from diphtheria. The contents of the crypt are made up of micrococci and epithelial debris.

Symptoms.—Chilly feelings, or even a definite chill, and aching pains in the back and limbs may precede the onset. The fever rises rapidly and in a young child may reach 105° F. on the evening of the first day. The patient complains of soreness of the throat and difficulty in swallowing. The appearance is that of acute illness. On examination the tonsils are seen to be swollen and the crypts present the characteristic exudate. The pharynx is usually inflamed and the uvula may be œdematous. The tongue is furred, the breath is heavy and foul, and the urine is highly colored and loaded with urates. In children the respirations are usually rapid and the pulse increased in rapidity. Swallowing is painful and the voice often becomes nasal. Slight swelling of the cervical glands is present. About the third to fifth day the temperature falls, often by crisis, and the symptoms lessen rapidly.

In epidemic cases the fever may be very high, the adenitis considerable, and even the deeper tissues may be involved. The complications are very serious: endocarditis, pericarditis, pneumococcic peritonitis, and pneumonia. In the Boston epidemic the clinical sequence was not unlike that in rheumatic fever—sore throat, adenitis, multiple arthritis, endocarditis, and pneumonia. Febrile albuminuria is common and acute nephritis may follow. A diffuse erythema may simulate scarlet fever. Acute otitis media is a frequent complication in children. Sinus infection may occur. Phlebitis is an occasional complication. Relapses are not uncommon and the tonsils may remain enlarged. Occasionally paralyzes follow the streptococcus tonsillitis which are identical with those of diphtheria. In some years acute pleurisy is a common complication; it may be fibrinous or sero-fibrinous.

In the sporadic and mild epidemic form it is rare to see a fatal case, but

in severe outbreaks the mortality from complications may be three or four per cent. There were about 50 deaths in the Boston epidemic.

A necrotic form is described, usually in young adults, with fever for some weeks; adenitis and enlargement of the liver and spleen are found. There may be a marked increase in the mononuclear cells. In the tropics a form of acute tonsillitis due to mycotic infection is described; monilia, saccharomyces, oidium, etc., may be responsible. There are creamy white patches on the tonsils which may extend to the soft palate, pharynx and larynx.

Diagnosis.—It may be difficult to distinguish tonsillitis from diphtheria. In the follicular form, the individual yellowish-gray masses, separated by the reddish tonsillar tissue, are very characteristic; whereas in diphtheria the membrane is ashy-gray and uniform, not patchy. A point of the greatest importance in diphtheria is that the membrane is not limited to the tonsils, but creeps up the pillars of the fauces and appears on the uvula. The diphtheritic membrane, when removed, leaves a bleeding, eroded surface; whereas the exudation of lacunar tonsillitis is easily separated, and usually there is no erosion beneath it. In all doubtful cases cultures should be made. The distinction from Vincent's angina rarely gives difficulty; smears should be examined and a culture made.

Treatment.—The patient should be in bed and stay there until the attack is over. The diet should be liquid with soft foods added if desired. Water should be taken in large amounts. The bowels should be moved freely by a calomel and saline purge and kept open by daily doses of saline if required. Aconite in full doses often acts beneficially in children. The combination of salol and phenacetine (of each, gr. iii-v, 0.2-0.3 gm.) can be given every three hours. Acetylsalicylic acid (gr. v, 0.3 gm.) is often useful in relieving symptoms. Ten grains (0.6 gm.) of Dover's powder or codein (gr. 1/2, 0.03 gm.) may be given at night. One of the best applications to the throat is a 10 per cent. solution of silver nitrate. Gargles should only be used if they do not cause pain. Solutions of iron, iodine, phenol (1 per cent.), hydrogen peroxide (25 per cent.) or an alkaline antiseptic mixture may be employed. The application of sodium bicarbonate directly to the tonsils sometimes gives relief. An ice bag to the neck is usually an advantage. In convalescence abundant nourishment and a tonic, such as the tincture of nux vomica (m xv, 1 c. c.), are useful. With repeated attacks and chronic tonsillar disease, removal of the tonsils is indicated.

XIII. ACUTE CATARRHAL FEVER

(*Acute Coryza*)

Definition.—An acute infection of the mucous membrane of the upper air passages associated with the presence of various organisms.

Etiology.—There are probably various organisms concerned; varieties of streptococci, staphylococci, pneumococci. *Micrococcus catarrhalis* and the influenza bacillus are found in cultures but they may be secondary invaders. In some cases there seems to be a very definite susceptibility which in certain cases is associated with chronic sinus infection or chronic tonsillar or nasal

infection. A sensitive mucous membrane may be a factor. A filterable virus has been suggested as the causal agent.

Prevailing most extensively in the changeable weather of the spring and early winter, coryza may occur in epidemic form, many cases arising in a community within a few weeks, outbreaks which are very like though less intense than the epidemic influenza. It is often a local outbreak in a house or school. The infection is spread by coughing, sneezing, etc.

Symptoms.—The patient feels indisposed, perhaps chilly, has slight headache, and sneezes frequently. In severe cases there are pains in the back and limbs. There is usually slight fever, the temperature rising to 101° F. The pulse is quick, the skin is dry, and there are all the features of a feverish attack. At first the mucous membrane of the nose is swollen, “stuffed up,” and the patient has to breathe through the mouth. A thin, clear, irritating secretion flows, and makes the edges of the nostrils sore. The mucous membrane of the tear-ducts is swollen, so that the eyes weep and the conjunctivæ are injected. The sense of smell and, in part, the sense of taste are lost. With the nasal catarrh there is slight soreness of the throat and stiffness of the neck; the pharynx looks red and swollen, and sometimes the act of swallowing is painful. The larynx also may be involved and the voice becomes husky or is even lost. If the inflammation extends to the Eustachian tubes the hearing may be impaired. In more severe cases the infection extends to the bronchi. Occasionally there is labial or nasal herpes. Usually within thirty-six hours the nasal secretion becomes turbid and more profuse, the swelling of the mucosa subsides, the patient gradually becomes able to breathe through the nostrils, and within four or five days the symptoms disappear, with the exception of the increased discharge from the nose and upper pharynx. There may be infection of the ears or sinuses. When the attacks are frequently repeated the disease may become chronic.

Diagnosis.—This is usually easy, but caution must be exercised lest the initial catarrh of measles or influenza be mistaken for a simple coryza.

Prophylaxis.—Avoidance of contact with infected persons and of places where people are crowded together should be of value. The use of antiseptic sprays and gargles is not often effectual. Vaccine therapy is of value in some cases, but often fails, especially when stock vaccines are used; autogenous vaccines in patients with repeated attacks are more successful. The removal of foci of infection is important, especially in the nose, tonsils and sinuses.

Treatment.—Many attacks are so mild that the patients are able to be about and attend to their work. If there are fever and constitutional disturbance, the patient should be kept in bed and take a simple fever mixture, and at night a drink of hot lemonade and a full dose of Dover's powder. For the local discomfort ephedrine solution is useful and sometimes gives immediate relief. Hexamine in full doses or active alkaline treatment by giving sodium bicarbonate may be useful. Ointments containing menthol and camphor may be applied locally. When the secretion is profuse atropine can be given in doses sufficient to lessen this. Acetylsalicylic acid or phenacetine (gr. v, 0.3 gm.) with codein (gr. ¼, 0.015 gm.) is often useful. Simple saline or oily sprays if employed should be used very gently. The vaccine treatment may be tried in persons subject to recurring colds, as a preventive.

XIV. FEBRICULA—EPHEMERAL FEVER

Definition.—Fever of slight duration, probably depending upon a variety of causes, some autogenous, others extrinsic and bacterial.

A febrile paroxysm lasting for twenty-four hours and disappearing completely is spoken of as ephemeral fever. If it persists for three, four, or more days without local affection it is referred to as febricula.

The cases may be divided into several groups:

(a) Those which represent mild or abortive types of the infectious diseases. It is not very unusual, during an epidemic of typhoid, scarlet fever, or measles, to see patients with some of the prodromal symptoms and slight fever, which persist for two or three days without any distinctive features. Possibly some of the cases are due to mild streptococcus infections.

(b) In a larger group of cases the symptoms develop with dyspepsia. In children indigestion and gastro-intestinal catarrh are often accompanied by fever. There may be headache, malaise, fever, vomiting and diarrhœa or constipation. Slight fever has been known to follow the eating of decomposing substances; but the gastric juice has remarkable antiseptic properties, and the frequency with which persons take articles which are "high" shows that poisoning is unlikely unless there is existing gastro-intestinal disturbance.

(c) Cases which follow exposure to foul odors. That a febrile paroxysm may follow a prolonged exposure to noxious odors has been suggested. The cases described under this heading are of two kinds: an acute, severe form with nausea, vomiting, colic, and fever, followed perhaps by collapse or coma; secondly, a form of low fever with or without chills.

(d) Many cases doubtless depend upon slight unrecognized lesions, such as tonsillitis or occasionally an abortive or larval pneumonia. Children are much more frequently affected than adults.

The *symptoms* set in, as a rule, abruptly, though in some instances there may have been preliminary *malaise* and indisposition. Headache, loss of appetite, and furred tongue are present. The urine is scanty and high-colored, the fever ranges from 101° to 103°; sometimes in children it rises higher. The cheeks may be flushed and the patient has the outward manifestations of fever. In children there may be bronchial catarrh with slight cough. Herpes on the lips is common. Occasionally in children the cerebral symptoms are marked and there may be irritation, restlessness, and nocturnal delirium. The fever terminates abruptly by crisis from the second to the fourth day; in some instances it may continue for a week.

The *diagnosis* generally rests upon the absence of local manifestations, particularly the skin rashes of the eruptive fevers, and the rapid disappearance of the pyrexia. The cases most readily recognized are those with acute gastro-intestinal disturbance. *Pyelitis* should always be kept in mind and its occurrence excluded. Careful search should be made for tonsillitis or sinusitis. Some of the cases may be due to mild attacks of *food poisoning*, in which thorough cultural studies of the stools are important. Mild attacks of *colon bacillus* infection have been suggested in some cases.

The *treatment* is that of mild pyrexia—rest in bed, a laxative, and a fever mixture containing nitrate of potassium and sweet spirits of nitre.

XV. INFECTIOUS JAUNDICE

There are several forms of infectious jaundice which may occur in epidemic form, due to a variety of organisms, some of which can be definitely determined. Outbreaks have occurred in many parts of the world and it was common in the great war. Certain forms may be separated.

(1) *Epidemic Catarrhal Jaundice*.—This seems to be a definite entity, the cause of which is obscure but due to a common source rather than to infection from one to another. There have been many localized epidemics in the United States recently which have been studied by Blumer. No proved etiological organism has been found. The early features are abdominal discomfort, gastric symptoms, diarrhoea or constipation, fever for two to four days, and malaise. Jaundice appears about the fourth day with pale stools and bile in the urine. The jaundice reaches a maximum in about ten days. There is enlargement of the liver and spleen, with tenderness of the former. Dilatation of the right heart is not uncommon but usually is present for a few days only. The mortality in a large series in soldiers was only 0.4 per cent. In some cases severe toxæmia or icterus gravis occurred.

(2) *Spirochætosis ictero-hæmorrhagica*.—(See page 291.)

(3) *Weil's Disease*.—It is difficult to know where to classify the disease described by Weil in 1886. It is by some regarded as synonymous with spirochætal jaundice but this does not seem to be proved. The features are more like those of epidemic catarrhal jaundice with marked splenic enlargement, fairly frequent hæmorrhagic features, and a high mortality. It would be an advantage if the designation "Weil's Disease" was dropped.

(4) A form of *hæmorrhagic jaundice* with severe features has been described in some districts on the Mediterranean. The etiology is unknown. There is acute fever with jaundice appearing about the fourth day. The liver is enlarged and hæmorrhagic features are marked. The mortality is high, death usually occurring in the second week.

In *treatment*, rest is important with milk diet and large amounts of water, which should be given by bowel or by duodenal tube if there is vomiting. Alkalies should be given freely as potassium citrate and sodium bicarbonate. The bowels should be kept open by salines and enemata. Judging from the excellent results in ordinary catarrhal jaundice Lyon's method of gall-duct drainage should be most useful. The duodenum should be irrigated with mild antiseptic solutions.

XVI. MILK-SICKNESS

This disease prevails in certain districts of the United States, mostly west of the Alleghany Mountains, and is connected with the affection in cattle known as the *trembles*. It prevailed extensively in the early settlements in certain of the western states and proved very fatal. The general opinion is that it is communicated to man only by eating the flesh or drinking the milk of diseased animals. The butter and cheese are also poisonous. In animals, cattle and the young of horses and sheep are most susceptible. It is stated that cows giving milk do not themselves show marked symptoms unless driven

rapidly, and, according to Graff, the secretion may be infective when the disease is latent. When a cow is very ill, food is refused, the eyes are injected, the animal staggers, the entire muscular system trembles, and death occurs in convulsions, sometimes with great suddenness. Fortunately, the disease has become rare. No definite pathological lesions are known. Jordan and Harris studied a New Mexico epidemic (1908) and found a bacillus (*B. lactimorbi*) with cultures of which the disease may be reproduced in other animals. Another view is that animals fed on white snake-root or the ragless goldenrod may develop "trembles" and that the disease can be contracted by drinking the milk from affected cows. Bulger *et al.* state that experimental animals show ketosis, lipæmia and a tendency to hypoglycæmia.

In man the *symptoms* are those of a more or less acute intoxication. After a few days of uneasiness and distress the patient is seized with pains in the stomach, nausea and vomiting, fever and intense thirst. There is usually obstinate constipation. The tongue is swollen and tremulous, the breath is extremely foul, and, according to Graff, is as characteristic of the disease as is the odor in small-pox. Cerebral symptoms—restlessness, irritability, coma, and convulsions—are sometimes marked, and a typhoid state may gradually be produced in which the patient dies.

The duration is variable. In the most acute form death occurs within two or three days. It may last for ten days, or even for three or four weeks. Graff states that insanity occurred in one case. The *treatment* is symptomatic, rest, liquid diet, abundance of fluid and carbohydrates, and free elimination.

XVII. GLANDULAR FEVER: INFECTIOUS MONONUCLEOSIS

Definition.—An infectious disease, usually in children, developing, as a rule, without premonitory signs, and characterized by slight redness of the throat, high fever, swelling and tenderness of the lymph-glands of the neck, particularly those behind the sterno-cleido-mastoid muscles. The fever is of short duration but the enlargement of the glands persists for ten days to three weeks. In children acute adenitis of the cervical and other glands with fever had been noted by many observers, but Pfeiffer in 1889 called special attention to it under the name of *Druesenfieber*.

Etiology.—It may occur in epidemic form. West, of Bellaire, Ohio, described an epidemic of 96 cases in children between the ages of seven months and thirteen years. Bilateral swelling of the carotid lymph-glands was a most marked feature. In three-fourths of the cases the post-cervical, inguinal, and axillary glands were involved. The mesenteric glands were felt in 37 cases, the spleen was enlarged in 57, and the liver in 87 cases. Coryza was not present, and there were no bronchial or pulmonary symptoms. The nature of the infection has not been determined.

Symptoms.—The onset is sudden and the first complaint is of pain on moving the head and neck. There may be nausea and vomiting and abdominal pain. The temperature ranges from 101° to 103° F. The tonsils may be a little red and the lymphatic tissues swollen, but the throat symptoms are transient and unimportant. On the second or third day the enlarged glands appear, and during the course they vary in size from a pea to a goose-egg.

They are painful to the touch, but there is rarely any redness or swelling of the skin, though at times there is some puffiness of the subcutaneous tissues of the neck, and there may be difficulty in swallowing. The liver and spleen are enlarged and tender in many cases. The leucocytes are increased, 15,000 to 20,000, due to an increase (75 to 85 per cent.) in mononuclear cells of a lymphoblastic type. The return to normal may take weeks. In some instances there has been discomfort in the chest and a paroxysmal cough, indicating involvement of the tracheal and bronchial glands. The swelling of the glands persists from two to three weeks. Among the serious features are the termination of the adenitis in suppuration, which seems rare (though Neumann met with it in 13 cases), and hæmorrhagic nephritis. Acute otitis media and retro-pharyngeal abscess have been reported. The outlook is generally favorable.

Diagnosis.—The situation of the swelling excludes mumps. The similarity to leukæmia may require time to make a diagnosis but the severe features of leukæmia are lacking. Adenitis secondary to local infection can be excluded by the absence of a local focus and the differential count. The blood findings exclude Hodgkin's disease and are also against acute tuberculous adenitis. Time may be required in addition. The treatment is symptomatic.

XVIII. MILIARY FEVER—SWEATING SICKNESS

The disease is characterized by fever, profuse sweats, and an eruption of miliary vesicles. It prevailed and was very fatal in England in the fifteenth and sixteenth centuries, and was made the subject of an important memoir by Johannes Caius, 1552. Hirsch gives a chronological account of 194 epidemics between 1718 and 1879, many of which were limited to a single village or to a few localities. Occasionally the disease has become widely spread. An epidemic of some extent occurred in France in 1887. Slight epidemics have occurred in Germany, Austria and Switzerland. They are usually of short duration, lasting only for three or four weeks—sometimes not more than seven or eight days. As in influenza, a large number of persons are attacked in rapid succession. In the mild cases there is only slight fever, with loss of appetite, and erythematous eruption, profuse perspiration, and an outbreak of miliary vesicles. The severe cases present the symptoms of intense infection—delirium, high fever, profound prostration, and hæmorrhage. The death-rate at the outset of the epidemic is usually high, and, as is so graphically described in the account of some epidemics of the Middle Ages, death may occur in a few hours. The treatment is symptomatic.

XIX. FOOT-AND-MOUTH DISEASE—EPIDEMIC STOMATITIS— APHTHOUS FEVER

Foot-and-mouth disease is an acute infectious disorder met with chiefly in cattle, sheep, and pigs, but attacking other domestic animals. It is of extraordinary activity, and spreads rapidly. The nature of the ultra-microscopic virus has not been determined. In cattle, after a period of incubation

of three or five days, the animal becomes feverish, the mucous membrane of the mouth swells, and little grayish vesicles the size of a hemp seed begin to develop on the edges and lower portion of the tongue, on the gums, and on the mucous membrane of the lips. They contain at first a clear fluid, which becomes turbid, then they enlarge and gradually become converted into superficial ulcers. There is pytalism, and the animals lose flesh rapidly. In the cow the disease is also seen about the udder, and the milk becomes yellowish-white in color and of a mucoid consistency.

The transmission to man is by no means uncommon by drinking the milk, eating milk products or by contact. The onset is with chilly sensations, general malaise, fever, and discomfort in the mouth. Vesicles appear in the mouth and pharynx, on the lips and occasionally on other parts. The vesicles rupture and shallow ulcers result which gradually heal. There is considerable discomfort from the mouth condition and sometimes salivation. In some epidemics there has been a hæmorrhagic tendency. Severe toxæmia is unusual. The ordinary course is from ten days to three weeks. Recovery is the rule but a mortality of 8 per cent. occurred in one epidemic. When the disease is prevalent in cattle, all milk should be boiled. Patients should be isolated and the secretions from the mouth destroyed. The *treatment* is symptomatic for the general condition, with local measures in the form of potassium permanganate solution as a mouth wash and the application of silver nitrate to the ulcers.

XX. PSITTACOSIS

A disease in birds, characterized by loss of appetite, weakness, diarrhœa, convulsions, and death. A disease in man characterized by an atypical pneumonia, great weakness and depression, and signs of a profound infection, somewhat like typhoid fever, has occurred from infection from birds, particularly parrots. There have been house epidemics with a high rate of mortality. The disease was widespread in 1929-30 with a number of deaths. The infectious agent is apparently a filterable virus. In *treatment*, the serum from convalescents has been used. Otherwise it is symptomatic.

XXI. ROCKY MOUNTAIN SPOTTED FEVER; TICK FEVER

Definition.—An acute disease, occurring in certain of the western states, of the United States, conveyed by ticks, characterized by chills, fever, general pains and a macular rash, becoming hæmorrhagic.

Etiology and Pathology.—The disease prevails especially in Montana and Idaho but occurs less frequently in other western and Pacific states. It is most prevalent in the spring and summer and among those who work in the fields and woods. The etiological agent is probably one of the Rickettsia group. It is conveyed by a tick (*Dermacentor andersoni*) which is apparently infected by biting wild animals, squirrels, etc. The disease is readily conveyed to monkeys and guinea-pigs. An attack gives immunity which is transmitted to the offspring. The specific microscopic lesions are endothelial proliferation; local necrosis of endothelium and thrombosis. Perivascular accumulation of cells is common.

Symptoms.—After an incubation of three to ten days, the onset is sudden with a chill, fever and severe pains, especially in the arms and legs. The fever is high and with it are the general features of an acute infection. The *rash* appears from the second to the sixth day, is macular, gradually becomes darker and finally hæmorrhagic. It often begins on the extremities and then spreads to the body. The skin is often swollen. Hæmorrhages from the mucous membranes may occur. There is usually a moderate leucocytosis. The course averages about four weeks, the fever falling by lysis. The mortality varies greatly with locality, reaching 70 per cent. in Montana but in Idaho being below 5 per cent.

Diagnosis.—Typhus and typhoid fever are the diseases most likely to cause difficulty. The former disease is not likely to occur in these localities and its course is more acute and shorter. The specific findings of typhoid fever are lacking. In some reported cases which suggest this disease, a tick has been found in the auditory canal.

Treatment.—Protection against ticks and their destruction are important in prevention. The treatment of the disease is that of typhus fever with special attention to the circulation. Serum from a convalescent would seem worth a trial. A vaccine from infected ticks is successful in prevention in animals.

XXII. SWINE FEVER

A few cases have been described from accidental inoculation in the preparation of cultures and in making post mortems upon pigs. In the course of from twelve hours to three days there is swelling of the fingers of the affected hand, which have a blue-red color, and small nodules form. In some of the instances the course has been like that of a painful erythema migrans, with swelling of the lymph-glands. A specific serum has been used with success.

XXIII. TRENCH FEVER

This is an acute infection, with a short period of fever, followed by a second rise or by two or three or more paroxysms of one or two days' duration. The causal organism has not been identified positively. There is evidence suggesting that it may be a form of Rickettsia. The organism is transmitted by the louse. The disease was first recognized in 1915 during the War. As it is not likely to be prevalent in civil life only a brief description is necessary.

The disease usually sets in acutely with chilliness, headache, and general pains, the latter sometimes of great severity. The fever is usually not high and of two or three days' duration. After an afebrile period one or more recurrences lasting for one or two days are very characteristic. In some instances the fever lasted for four or five days. The symptoms usually subsided during the afebrile period. The greatest complaint was of *tender shins*. As a rule there was no swelling or redness, and the pain was usually most marked at night. The course of the fever and the tender shins are the two most important aids in diagnosis. Many cases were regarded at first as influenza.

There is no specific treatment. Complete rest is important and acetylsalicylic acid sometimes relieved the pain. A local application of a saturated solution of magnesium sulphate sometimes gave relief.

XXIV. EPIDEMIC DIAPHRAGMATIC PLEURODYNIA

This was first described by W. C. Dabney in 1888 from Virginia, who quoted the designation "devil's grip." Outbreaks occurred in various localities in 1923 and 1924. The epidemic occurrence suggests an infectious agent and Small has described a plasmodium. The mode of transmission is not known. The *onset* is sudden, often with a chill, and with a rapid elevation of temperature to 102°-104°. The principal *symptom* is *pain* in the epigastrium, lower thorax and back which is aggravated by movement. Its severity may render breathing difficult. With this there is extreme tenderness which may persist after the pain has gone. Headache, sweating and a rapid pulse occur. There are no signs of lung or pleural involvement. There may be a return of the symptoms after the first acute features are over. The prognosis is good and the treatment is symptomatic.

XXV. SIX (SEVEN) DAY FEVER

This is a fever like dengue of about a week's duration, probably caused by a spirochæte, *Leptospira hebdomadis*. It occurs chiefly in India and Japan. The spirochæte is found in the blood from the second to the fourth day and also in the urine, where it may be found for some weeks after the fever has gone. The disease begins suddenly, the temperature shows marked remissions, skin rashes are common, usually a blotchy erythema, sometimes with petechiæ. It terminates on the sixth or seventh day by crisis, and when the date of onset is known the defervescence may be predicted within a few hours. The treatment is symptomatic.

XXVI. MISCELLANEOUS INFECTIONS

Phlebotomus Fever.—(*Sandfly Fever*; *Three-day Fever*). This is due to a filtrable virus conveyed by the sandfly, *Phlebotomus papatassii*. The disease occurs in India, Persia, Mesopotamia, Egypt and southeastern Europe. The onset is sudden and the features are those of an acute febrile illness with fever for two to three days. There is a leucopenia early and leucocytosis later. Death is very rare. Influenza and malaria are the diseases most likely to cause difficulty in diagnosis. The treatment is symptomatic.

Verruga peruviana.—This is a febrile disease occurring in parts of the Andes in Peru characterized by tubercles of the skin much like yaws. It was formerly thought to be closely related to, if not a stage of, Oroya fever but is now regarded as separate. The attacks begin with malaise, fever, marked pains in the joints and muscles, followed by a severe anæmia. There is difference of opinion as to the occurrence of rod-shaped bodies (Barton's bodies) in the red cells. The eruption appears as papules or tubercles varying

in size from that of a pea to a chestnut. They gradually assume a warty form. The face, neck, and extremities are the common sites but the eruption may be general. The mucous membranes may be involved. Successive crops appear for a time. Ulceration is common; healing occurs gradually leaving a scar. The duration is four or six months to a year. Death occurs in from 10 to 25 per cent. In the prevention avoidance of infected areas is important. Local treatment is indicated for the lesions.

Oroya Fever.—This occurs in Peru, is possibly transmitted by an insect, and presents fever, marked anæmia and adenitis with a high mortality. Some students of the disease believe the cause is an organism (*Bartonella bacilliformis*) found in the red cells of patients with the disease. The disease shows irregular fever, severe pains and adenitis. There is extreme anæmia of the pernicious type with the red cells reduced to a million and a considerable leucocytosis. The mortality is 25 to 40 per cent. There is no specific treatment.

Tsutsugamushi Fever (Japanese River Fever).—This is an acute disease occurring in Japan transmitted by the bite of a trombidium (mite). The organism is possibly one of the Rickettsia group. At the site of the bite a small area of necrosis results. The regional lymph nodes enlarge, fever follows with the general symptoms of an acute infection. About a week after the onset a rash appears on the face and spreads to the trunk and limbs. It is macular and papular, becoming hæmorrhagic. The fever lasts two to three weeks. The mortality is given as 20 to 50 per cent. Treatment is symptomatic.

Gangosa.—This is characterized by an ulcerative process which involves the pharynx, larynx, mouth and nose. It occurs in the West Indies and some of the Pacific islands. There is doubt as to the nature of the disease; some regard it as akin to yaws, others to dermal Leishmaniasis. The process begins usually in the palate and gradually spreads with ulceration until the mouth, nose, palate and sometimes the larynx and eyes are destroyed. Leprosy, syphilis, yaws and Leishmaniasis have to be considered. The process may stop or go on until death from sepsis and exhaustion. Arsphenamine and antimony should be used, with local treatment of the ulceration.

Climatic Bubo.—In this there is inguinal adenitis with a tendency to chronicity and occasional suppuration. The condition is widespread, especially in parts of Africa and Asia. The causal agent is unknown. Males only are affected and the condition often follows intercourse with a black woman. There is irregular fever followed by marked adenitis of the inguinal glands which is painful and chronic. Suppuration may result; in any case some thickening remains. Plague, venereal buboes and adenitis secondary to an infection on the feet or legs have to be excluded. In treatment rest is advisable and local applications to relieve pain. Removal of the glands is not advisable. Operation is advisable if suppuration occurs. The use of foreign protein intravenously has been advised.

Exanthema Subitum.—This has an acute onset. There is high fever for three to five days. As the temperature falls a morbilliform rash appears mostly on the trunk and little on the mucous membranes. It lasts about four days. There is leucopenia with 80-85 per cent. of lymphocytes. The course is mild with no complications or sequels described.

SECTION II

DISEASES DUE TO PHYSICAL AGENTS

I. SUNSTROKE; HEAT EXHAUSTION

(*Insolation, Thermic Fever, Siriasis*)

Definition.—Under these terms are comprised certain manifestations following exposure to excessive heat, of which thermic fever or sunstroke, heat exhaustion, and heat cramps are the common forms.

History.—It is one of the oldest of recognized diseases. The case of the son of the Shunammite woman (2 Kings, IV) is perhaps the oldest on record. The Arabians called the symptoms due to excessive heat “Siriasis,” after Sirius, the Dog Star. Cardan recognized it in the sixteenth century and thought it was apoplexy due to heat—*morbus attonitus*. In the eighteenth century Boerhaave regarded it as phrenitis. It was not until the nineteenth century that the Anglo-Indian surgeons and the physicians of the United States gave us a full knowledge of the different affections due to excessive heat. Various classifications have been suggested, but two chief forms are everywhere recognized—heat exhaustion and thermic fever or sunstroke—to which Edsall added the remarkable heat cramps which occur in persons working under very high external temperatures.

Distribution.—Sunstroke occurs in the tropics and in temperate regions during protracted heat waves. It is common in the Atlantic Coast cities of the United States during the hot spells of summer. Heat exhaustion is frequently met with in conditions similar to those in which sunstroke takes place, and it is not infrequent in the engine-rooms of large steamships, less often in foundries. In the U. S. Navy in 35 years (to 1913) there were 20 deaths and 33 invalided on account of heat prostration (Fiske).

Heat Exhaustion.—In the tropics and in temperate regions during protracted heat waves many persons become depressed physically and are unable to work or take nourishment. In children the condition is very often associated with gastro-intestinal disturbances and fever. The true heat syncope is specially seen in persons who have not been in good health or who are in-temperate. The heat may be that of the sun or artificial heat, as in the engine-rooms of steamers. The symptoms begin with giddiness, nausea, an uncertain, staggering gait; there is pallor, the pulse is small, the heart’s action weak, the respirations rapid, and the patient may quickly become unconscious. Muscular spasms, often painful, are common. Externally the body may be clammy, with sweat, but as a rule the rectal temperature is decreased. In the axilla it may be as low as 95° or 96° F. From slight attacks, the patients recover rapidly when brought on deck; in other cases the unconsciousness may end in deep coma and death.

Sunstroke.—This is more common in men than in women and children, and is principally seen in persons exposed to the sun, who are too heavily clad, or who are addicted to alcohol. High humidity favors its occurrence. It is more common in Europeans than in the dark races, but in the United States negroes are often attacked. Some regard a decrease in the alkaline reserve with high lactic acid content of the blood and acidosis as important.

MORBID ANATOMY.—Rigor mortis occurs early and putrefactive changes may come on with great rapidity. The venous engorgement is extreme, particularly in the cerebrum. The left ventricle is contracted (Wood) and the right chamber dilated. The blood is usually fluid; the lungs are intensely congested. Parenchymatous changes occur in the liver and kidneys. There may be punctate hæmorrhages in the nervous system and changes in the nerve cells.

SYMPTOMS.—The patient may be struck down and die within an hour, with symptoms of circulatory failure, dyspnœa, and coma. This form, sometimes known as the asphyxial, occurs chiefly in soldiers and is graphically described by Parkes. Death may be almost instantaneous, the victims falling as if struck upon the head. The more usual form comes on during exposure, with pain in the head, dizziness, a feeling of oppression, and sometimes nausea and vomiting. Visual disturbances are common, and a patient may have colored vision. Diarrhœa or frequent micturition may supervene. Insensibility follows, which may be transient or which deepens into profound coma. The patients are usually admitted to hospital in an unconscious state, with the face flushed, the skin hot, the pulse rapid and full, and the temperature ranging from 107° to 110° F., or even higher. The breathing is labored and deep, sometimes stertorous. Usually there is complete relaxation of the muscles, but twitchings, jactitation, or very rarely convulsions may occur. The pupils may at first be dilated, but by the time the patients are admitted to hospital they are (in a majority) extremely contracted. Petechiæ may be present upon the skin. In the fatal cases the coma deepens, the cardiac pulsations become more rapid and feeble, the breathing becomes hurried and shallow and of the Cheyne-Stokes type. The fatal termination may occur within twenty-four or thirty-six hours. Favorable indications are the return of consciousness and a fall in the fever. The recovery in these cases may be complete. In other instances there are remarkable after-effects, the most constant of which is a permanent inability to bear high temperatures. Such patients become very uneasy when the thermometer reaches 80° F. in the shade. Loss of the power of mental concentration and failure of memory are troublesome sequelæ. Such patients are always worse in the hot weather. Occasionally there are convulsions, followed by marked mental disturbance. Dercum described peripheral neuritis as a sequence.

Many observers have called attention to a fever in the tropics which lasts for a few days, with no special symptoms other than those of pyrexia and weakness. This may be simply heat exhaustion. It is not uncommon in the southern states, where it may be mistaken for malaria or mild typhoid fever.

DIAGNOSIS.—It is rarely difficult to distinguish thermic fever from the malignant types of malaria and from the various other forms of coma. The diagnosis of heat exhaustion from sunstroke is readily made. In the one the skin is moist, pale, and cool, the pulse small and soft, and consciousness

may remain till near the end; whereas in the other there is high fever with early unconsciousness.

PROGNOSIS.—In the old, the infirm, and alcoholic subjects the mortality from sunstroke during a very hot wave may be as high as 30 or 40 per cent.

TREATMENT.—In heat exhaustion stimulants (ammonia and caffeine) should be given freely, and if the temperature is below normal the hot bath should be used. In sunstroke the indications are to reduce the temperature as rapidly as possible. Rubbing the body with ice is an excellent procedure to lower the temperature rapidly. The wet pack with an electric fan blowing on the patient or the bath may be used until the rectal temperature falls to

CHART XII.—CASE OF SUNSTROKE TREATED BY THE ICE-BATH; RECOVERY.

103°. Ice-water enemata may also be employed. Alkaline solutions should be given by bowel or intravenously. In the cases with intense asphyxia, and in which death may take place in a few minutes, free bleeding should be practised, a procedure which saved Weir Mitchell when a young man. For the convulsions, chloroform should be given at once. Antipyretics should not be employed. Lumbar puncture is useful.

Heat Cramps.—Persons doing heavy muscular work while exposed to a very high temperature are liable to attacks of severe cramp. The condition, which has been described very thoroughly by Edsall, occurs principally in stokers in the furnace-rooms of steamships and in workers in iron foundries. The spasms occur chiefly in the muscles of the calves, the arms, and sometimes in the abdomen; they are often of great intensity and very painful. A movement, pressure, or any stimulus, as electricity, may send the muscle into

spasm at once. In addition to ordinary cramps there are sometimes fibrillary contractions. The attacks may last for from 12 to 34 hours and are followed by muscular soreness and sometimes by great weakness. Warm baths with massage and morphia hypodermically usually give relief.

II. CAISSON DISEASE

(Compressed Air Disease; Diver's Paralysis)

Definition.—A disease of caisson workers and divers, due to a saturation of the tissues with nitrogen under the increased pressure. If the decompression takes place quickly, a too-rapid escape of bubbles of nitrogen occurs into the tissues and into the blood causing air embolism.

History.—The French writers, Bucquoy, Foley, and Bert, first studied the disease. Leyden recognized the anatomical changes. A. H. Smith and others in the United States contributed important papers, and the studies of Haldane, Leonard Hill, and Boycott have thrown light upon the etiology and means of prevention.

Etiology.—The cases are met with chiefly in workers in caissons and tunnels and in divers. Fat subjects are specially susceptible. "The higher the pressure and the shorter the period of decompression the greater is the risk" (Hill). In caissons the pressure is rarely 30 to 35 pounds, but in the St. Louis bridge the pressure reached as high as 45 to 50 pounds. Divers go down to 20 fathoms with a pressure of 53 pounds; the record depth attained by divers is 210 feet (Hill). The disease may occur in very deep mines. In building the St. Louis bridge across the Mississippi, among 352 workers there were 50 cases of paralysis and 14 deaths. In constructing the East River tunnels in New York, among 10,000 men employed there were 3,692 cases and 20 deaths resulted.

Pathology.—To Hoppe-Seyler, Bucquoy, and Paul Bert we owe a rational explanation of the disease. During compression the blood passing through the lungs becomes saturated with nitrogen, which is carried to the tissues until the whole body is saturated. "The mass of blood is about 5 per cent. of the body, and the capacity of the tissues to dissolve N is estimated by Boycott as 35 times that of the blood—in a fat man considerably more" (Hill). With active work it does not take long to effect complete saturation. During decompression the process is just the reverse. "The blood gives up N to the alveolar air and returns to the tissues for more. Those organs in which the circulation is rapid will yield up their N quickly, and those with a sluggish circulation slowly . . . and at the end of decompression a condition may be set up in which the slow tissues still hold, say 3 per cent. of N, while the blood can dissolve only 1 per cent. Herein we have a danger of bubbles forming" (Hill). The nitrogen in the body fluids begins to dissolve out as soon as the pressure is lowered. This is only harmful if the nitrogen separates in the form of bubbles. These form first in the venous blood and fatty tissues, in the synovial fluid of the joints, and in the nervous system. As a rule a very rapid reduction in pressure must occur before the formation of bubbles follows. The spinal cord may contain many air emboli, usually

more numerous in the white matter. This was the anatomical lesion determined by Leyden, who found fissuring and laceration of the cord, which explains the paraplegia. Pulmonary air embolism also occurs and is responsible for certain features. In an analysis of gas from the right heart, Erdman found 80 per cent. of N and 20 per cent. of CO₂.

Symptoms.—In slight cases within from half an hour to one hour after leaving the caisson, the patient has headache, giddiness and feels faint, symptoms which may pass off and leave no further trouble. In other instances the patients have severe pains in the extremities, usually the legs and the abdomen, sometimes associated with nausea and vomiting—attacks which the workmen usually speak of as “the bends.” The pains may be of the greatest intensity and associated with giddiness and vomiting. Paralysis, usually of the legs, comes on rapidly, and varies in degree from weakness to complete loss both of motion and sensation. This occurred in 15 per cent. of A. H. Smith’s cases and in 61 per cent. of the St. Louis cases. Monoplegia and hemiplegia are rare. In extreme instances the attacks resemble apoplexy; the patient rapidly becomes comatose and death occurs in a few hours. The paraplegia may be permanent, but in slight cases it gradually disappears and recovery may be complete. Late resulting features are spinal cord changes, chronic arthritis and deafness.

Prophylaxis.—The only safeguard is a gradual decompression, which obviates the risk of rapidly setting free the nitrogen from the tissues. Haldane and his colleagues introduced what they call the “Stage Method,” which is now widely adopted with the most beneficial results. For work in very high pressures the shifts should be short, not more than two hours.

Treatment.—The caisson workers found very early that the best remedy for “the bends” was immediate recompression, and A. H. Smith of New York introduced a medical air-lock for the Brooklyn bridge workers. The workers should live and sleep not far from the works, where such an air-lock should be provided for immediate treatment. Cases with severe symptoms may be saved by recompression. Hot fomentations, massage and hypodermics of morphia may be necessary for the extreme pains.

III. MOUNTAIN OR ALTITUDE SICKNESS: ANOXÆMIA

Definition.—An illness associated with exposure to low atmospheric pressures and due to lack of oxygen, characterized by cyanosis, nausea, headache, intestinal disturbances, hyperpnœa and sometimes syncope.

Etiology.—The symptoms are directly referable to want of oxygen produced by the diminished pressure of the atmosphere. Haldane, Douglas and Henderson made an exhaustive study of the process of accommodation in a five weeks’ residence at the top of Pike’s Peak. After acclimatization the symptoms disappeared, but dyspnœa, blueness and periodic breathing are apt to follow exertion. The alveolar carbon dioxide pressure was reduced from about 40 mm. to about 27 mm. during rest, which corresponded to an increase of about 50 per cent. in the ventilation of the lung alveoli. This process of accommodation is associated with a remarkable increase in the red blood cells and hæmoglobin to 120 to 150 per cent. These authors conclude

that acclimatization is largely due to increased secretory activity of the alveolar epithelium, to greater lung ventilation and to increased hæmoglobin production.

The disturbance known as "Aviators' Sickness" also involves the problem of a low barometric pressure. The pressure of the oxygen in the arterial blood in high altitudes may be higher than in the alveolar air. Active secretion of oxygen occurs in the lungs; that is, the passage of oxygen is accelerated and this apparently has a selective action. There is a tendency to bradycardia in aviators after a sudden descent, probably part of a vagobulbar syndrome.

Symptoms.—These usually begin at altitudes of 12,000-15,000 feet. Dyspnoea is usually the first symptom, made markedly worse by exertion and accompanied by cyanosis. Headache, nausea, vomiting, hyperpnoea, epistaxis and frequent micturition follow with marked muscular weakness, so that even slight exertion is difficult. The muscular weakness has been particularly marked in mountain climbing at high altitudes. Of especial interest are the *mental changes*, which are common in aviation, especially when a high altitude is reached quickly. There is mental inaccuracy with lethargy and disturbance of the psychical functions, especially judgment and memory. Syncope may result. Ringing in the ears followed by deafness is common. Death has occurred in balloon ascents.

Treatment.—The condition may be prevented by the use of apparatus to supply a proper amount of oxygen. If symptoms have appeared the patient should be kept as quiet as possible, given oxygen if available, and brought down to a lower altitude.

IV. GAS POISONING

Carbon Monoxide.—*Acute* poisoning is comparatively frequent and due especially to illuminating gas, with many cases caused by the exhaust from motor cars in closed or poorly ventilated places. It is a common method of suicide. The so-called "water gas" contains much more carbon monoxide than that manufactured by dry distillation. The only effect of carbon monoxide is through its combination with hæmoglobin resulting in lack of oxygen to the tissues. Damage to the brain cells results fairly quickly—within a few hours—and hence continued coma is probably due to œdema of the brain and degenerative processes rather than to the lack of oxygen, as the greater part of the carbon monoxide is given off in four or five hours. The frequency of *chronic* poisoning is difficult to state. In occupations about furnaces in many trades, in mining (carbon monoxide is derived from the explosive) and in garages there are possibilities of poisoning.

The main *symptoms* are a general feeling of illness, headache, vertigo, nausea and vomiting, and marked muscular weakness. If the dose is large the subject becomes drowsy and then unconscious. Muscular twitchings and convulsions often occur. At this stage the respiration is usually rapid, the pulse is rapid also, and usually weak. Cyanosis is marked, accompanied by a peculiar redness of the skin. The blood has a bright red color. Pulmonary complications are important, particularly pneumonia (less frequent if the carbon dioxide-oxygen treatment is used) and they may appear some time after the poisoning. Recovery may result after coma has lasted for many hours

but its duration for twenty-four hours is usually fatal. A great variety of nervous sequels have resulted, neuritis, tremor, paralyses, psychoses, visual disturbances, etc. In *chronic* poisoning, headache, vertigo, nausea, weakness and sometimes mental disturbance are common.

The *diagnosis* is rarely in doubt in the acute cases. The odor of the breath may be characteristic and the spectroscopic test is positive.

Treatment.—The patient should be removed from the poisoned air at once and then the essential need is vigorous breathing “to draw oxygen in and wash the carbon monoxide out.” Oxygen inhalation is required. Venesection and transfusion are not helpful and may be harmful. Artificial respiration is useful in starting breathing if this has stopped. Henderson and Haggard (Jour. Am. Med. Assn. 1922, 79, 1137) as a result of their thorough investigation point out that the best stimulus for deep breathing is to supply enough carbon dioxide (5 per cent.) with oxygen for this purpose. They have devised a special apparatus which should be kept ready for use by the emergency crews of gas companies and in large hospitals. The mask may be held over the face while artificial respiration is carried on if the breathing is feeble. The results have been very satisfactory. If the apparatus is not available, the best method is to introduce oxygen into the pharynx by a small tube passed through the mouth or nose, using artificial respiration if the breathing is feeble. The less one does in addition the better. The use of apparatus to aid respiration is advised against.

Carbon Bisulphide.—This is used to treat india rubber and poisoning may occur. Headache, vertigo, insomnia and depression are common. Subsequently areas of anæsthesia and paræsthesias of various kinds may be found. Vision and taste may both show changes. A great variety of symptoms from disturbance of the nervous system results and organic nervous diseases may be closely simulated. Prophylactic measures are usually successful and the treatment is symptomatic.

Benzene (Benzol) Poisoning.—Benzene is used extensively in trades for its solvent qualities, especially in rubber manufacture, in dry cleaning and in quick drying paints. *Benzine* is a petroleum distillate and much less toxic than benzene. A commonly used material called “solvent naphtha” is a combination of crude benzene, toluene and xylene. *Acute* poisoning from benzene usually occurs in the refining works, death resulting rapidly. *Chronic* poisoning results from continued exposure with absorption by the skin or respiratory tract. The symptoms are headache, general malaise, nausea, vomiting, and abdominal pain. Hæmorrhages may occur from the nose, mouth, stomach and uterus. Extreme *anæmia* develops in which the red cells may fall to a million or less with marked leucopenia. Aplastic anæmia may follow. The outlook in the severe cases is grave. *Prophylaxis* evidently consists in preventing the possibility of absorbing the material but this is difficult and small amounts may cause poisoning. In the chronic cases with anæmia the usual treatment and blood transfusion are indicated.

Gas-poisoning in War.—Our interest is now concerned with the after-effects in those who were gassed. Several possibilities exist. (1) The psychical result is a factor in some cases, but time should help the majority of them. (2) Actual damage to the respiratory tract. Some show this but the exact effects are sometimes difficult to estimate; chronic bronchitis, emphysema and

fibroid changes are the most important. (3) Changes in the respiratory exchange which may be a permanent result. (4) There is no evidence that there is any increased liability to tuberculosis.

V. CAR SICKNESS AND SEA SICKNESS

These are not diseases but combinations of symptoms which have much in common. The causes are various and in different individuals the factors are not necessarily the same. The disturbance due to the movements and the difficulty of adjustment to them are important factors, in which the eyes, the labyrinths and the general sensorium are concerned. The disturbance of orientation is important, but other factors, such as unpleasant odors or poor ventilation, play a part. A psychical factor operates in some patients, as when sea-sickness occurs before the vessel has sailed or from the sight or hearing of others who are ill. Some persons suffer when riding in a closed motor car for more than a short time but not in an open car. In many cases the absence of fresh air is certainly a predisposing factor. The necessity of exertion has sometimes a marked effect in prevention. Constipation is apparently a factor in many people. The subjects of migraine are prone to all these forms of disturbance. The individual reaction varies greatly; some are never ill on a large steamer but suffer in a sail boat or launch if there is much motion, and *vice versa*. Many succumb on a voyage only if rough weather comes on early in the trip; after a couple of days with ordinary weather they have their "sea legs" and are immune.

Symptoms.—These are divided into those affecting particularly the nervous system and the digestive tract. One or other may predominate but both usually occur. There is generally some disturbance of the nervous system. In train and motor car sickness there are usually distress, headache, nausea and often vomiting. In some persons the passing of a long train of cars on another track is apt to cause symptoms, pointing to ocular disturbance as responsible. In train sickness there may be persistent retching and vomiting, sometimes followed by marked prostration. In sea sickness there is general discomfort, perhaps with headache, salivation and nausea, soon followed by retching and vomiting. Usually there is constipation but occasionally there may be frequent stools, at first faecal and later composed largely of mucus. The vomiting may be continuous and, as the contents of the stomach are soon disposed of, the vomitus consists of mucus, bile and watery fluid. Anorexia is common and there is marked pallor. Headache, vertigo and marked depression may occur. In extreme cases, as is seen in a rough Channel crossing, there may be severe collapse. After some days the loss of fluids is marked; there is obstinate constipation and scanty urine, and acidosis may result. The exhaustion and prostration may be marked. The duration is rarely more than a few days, unless rough weather continues, and recovery is rapid. Some suffer for the whole voyage but death probably never results.

Prevention.—For those who are subject to train sickness the diet should be very simple for a day before the journey and the bowels should be freely opened. The use of bromide (gr. xv. 1 gm.) three times a day for two days before the journey is often effectual. If the journey is a long one the bromide

should be taken during it. The securing of good ventilation is important. To lessen the chance of sea sickness, the diet should be very simple for several days before sailing and the bowels freely opened. As constipation is common it is well to take laxatives and drink freely of water. Many drugs are employed. Of these the bromides are useful, taken for two or three days before and during the first half of the voyage. Chloretone (gr. v to x, 0.3 to 0.6 gm.) is useful, taken in the same way. On the ship some are better to stay in their berth if the weather is rough; others do better on deck. There is no rule. A hot drink before getting up in the morning is useful.

Treatment.—With sea sickness the patient is better in bed and kept warm. Bromide or chloretone may be taken if vomiting does not prevent. Atropine in full dosage is sometimes useful. The bowels should be kept open if possible, for which salines are usually best. Care should be taken to give very simple food after the vomiting ceases but sometimes most unusual food is desired. The taking of alkaline fluid freely is important. In very severe cases the giving of morphine and atropine hypodermically is useful. Alcohol is regarded by many as helpful but for the majority it is not of value. Recovery is usually aided by the patient being on deck after the acute features are over. In severe cases with acidosis, the administration of fluids and dextrose solution (subcutaneously or by bowel) is useful.

VI. POISONING FROM RADIO-ACTIVE SUBSTANCES

There is great danger in handling radio-active substances (mesothorium and radium) and in those exposed to the rays from these substances, there are deposits of radio-active substances in the bones which are fixed and give off emanations, 95 per cent. of which are alpha rays. These injure the adjoining bone marrow with the production of a severe anæmia and occasionally leucæmia. The anæmia is often clinically of the aplastic form but may be more like ordinary pernicious anæmia. There is a marked leucopenia. Necrosis of bones often results, especially in the jaw, and is probably a radiation osteitis with secondary infection. The *diagnosis* is made by finding emanations in the expired air or from the body by means of the gamma electroscope. After death the diagnosis is made by special photographic methods from the bones or the bone ash. In the organs the radio-activity can be demonstrated by the alpha electroscope. The *prognosis* is very grave but better in the mesothorium than in the radium cases. The *treatment* is symptomatic, every care being taken to keep the mouth clean and prevent sepsis. The usual treatment for anæmia is given. The prevention is varied depending on the kind of exposure. In industrial poisoning the habit of moistening a brush, used in painting luminous dials, in the mouth has been responsible for a number of cases.

SECTION III

THE INTOXICATIONS

I. ALCOHOLISM

(a) **Acute Alcoholism.**—When a large quantity of alcohol is taken, the influence is chiefly on the nervous system, and is manifested in muscular incoordination, mental disturbance, and, finally, narcosis. The individual presents a flushed, sometimes slightly cyanosed face, the pulse is full, respirations deep but rarely stertorous. The pupils are dilated. The temperature is frequently below normal, particularly if the patient has been exposed to cold. Perhaps the lowest reported temperatures have been in cases of this sort. An instance is on record in which the patient on admission to hospital had a temperature of 24° C. (ca. 75° F.), and ten hours later the temperature had not risen to 91° F. The unconsciousness is rarely so deep that the patient cannot be roused to some extent, and in reply to questions he mutters incoherently. Muscular twitchings may occur, but rarely convulsions. The breath has a heavy alcoholic odor. The respirations may be slow; in one case they were only six in the minute.

The *diagnosis* is not difficult, yet mistakes are frequently made. Persons are brought to a hospital by the police supposed to be drunk when in reality they are dying from apoplexy or uræmia. Too great care cannot be exercised, and the patient should receive the benefit of the doubt. In some instances the mistake arises from the fact that a person who has been drinking heavily has been stricken with apoplexy or fractured the skull. In apoplexy the coma is usually deeper, stertor is present, and there may be evidence of hemiplegia in the greater flaccidity of the limbs on one side. The diagnosis is considered in the section on uræmia.

Dipsomania is a form of acute alcoholism seen in persons with a strong hereditary tendency to drink. Periodically the victims go "on a spree," but in the intervals they are entirely free from any craving for alcohol.

(b) **Chronic Alcoholism.**—The harmful effects of alcohol are manifested (1) as a functional poison, as in acute narcosis; (2) as a tissue poison, in which its effects are seen on the parenchymatous elements, producing a slow degeneration; (3) in the formation of a habit with disastrous results on the moral character; and (4) as a checker of tissue oxidation. This leads to fatty changes and sometimes to a condition of general steatosis. Acidosis may occur.

The chief effects of chronic alcohol poisoning may be thus summarized:

Nervous System.—Functional disturbance is common. Unsteadiness of the muscles in performing any action is a constant feature. The tremor is best seen in the hands and in the tongue. The mental processes may be dull,

particularly in the early morning hours, and the patient is unable to transact any business until he has had his accustomed drink. Irritability of temper, forgetfulness, and a change in the moral character gradually come on. The judgment is seriously impaired, the will enfeebled, and in the final stages dementia may supervene. An interesting combination of symptoms in chronic alcoholics is characterized by peripheral neuritis, loss of memory, and pseudo-reminiscences—that is, false notions as to the patient's position in time and space, and fabulous explanations of real occurrences. The peripheral neuritis is not always present; there may be only tremor and jactitation of the lips, and thickness of the speech, with visual hallucinations. The mental condition was described by Jackson and by Wilks. Korsakoff speaks of it as a *psychosis polyneuritica*, and the symptom-complex is sometimes called by his name. The relation of chronic alcoholism to insanity has been much discussed. It is one of the important elements in the strain which leads to mental breakdown. Epileptiform attacks may result directly from chronic drinking. It is a hopeful form, and may disappear entirely with a return to habits of temperance.

There is a remarkable condition in chronic alcoholism termed "*wet brain*," in which a heavy drinker, who may perhaps have had attacks of delirium tremens, is drowsy or a little more befuddled than usual; gradually the stupor deepens until he becomes comatose, in which state he may remain for weeks. There may be slight fever, but there are no signs of paralysis and no optic neuritis. The urine may be normal. The lumbar puncture yields a clear fluid, but under high pressure. In one patient who died at the end of six weeks, there were the anatomical features of a serous meningitis.

No characteristic changes are found in the nervous system. Hæmorrhagic pachymeningitis is not very uncommon. There are opacity and thickening of the pia-arachnoid membranes, with more or less wasting of the convolutions. These are in no way peculiar to chronic alcoholism, but are found in old persons and in chronic wasting diseases. In the very protracted cases there may be chronic encephalo-meningitis with adhesions of the membranes. Finer changes in the nerve-cells, their processes, and the neuroglia have been described. The alcoholic neuritis will be considered later.

Digestive System.—Catarrh of the stomach is the most common symptom. The toper has a furred tongue, heavy breath, and in the morning a sensation of sinking at the stomach until he has had his dram. The appetite is usually impaired and the bowels are constipated. In beer-drinkers dilatation of the stomach is common.

Alcohol produces definite changes in the liver, leading ultimately to the various forms of cirrhosis. The effect is a primary degenerative change in the liver-cells. A special vulnerability of the liver-cells is necessary in the etiology of alcoholic cirrhosis. There are cases in which comparatively moderate drinking for a few years has been followed by cirrhosis; on the other hand, the livers of persons who have been steady drinkers for thirty or forty years may show only a moderate grade of sclerosis. For years before cirrhosis develops heavy drinkers may have an enlarged and tender liver, with at times swelling of the spleen. With the gastric and hepatic disorders the facies often becomes very characteristic. The venules of the cheeks and nose are dilated; the latter becomes enlarged, red, and may present the condition known as

acne rosacea. The eyes are watery, and conjunctivæ hyperæmic and sometimes bile-tinged.

The heart and arteries in chronic toppers show degenerative changes, and alcoholism is a factor in causing myocardial degeneration. Steell pointed out the frequency of cardiac dilatation in these cases.

Kidneys.—The influence of chronic alcoholism upon these organs is by no means so marked. According to Dickinson the total of renal disease is not greater in the drinking class, and he holds that the effect of alcohol on the kidneys has been overrated. Formad pointed out that in a large proportion of chronic alcoholics the kidneys are increased in size. The Guy's Hospital statistics support this, and Pitt notes that in 43 per cent. of the bodies of hard drinkers the kidneys were hypertrophied without showing morbid change. A granular kidney may result indirectly through the arterial changes.

It was formerly thought that alcohol was in some way antagonistic to tuberculous disease, but the reverse is the case and chronic drinkers are more liable to both acute and pulmonary tuberculosis. It is probably a question of altered tissue-soil, the alcohol lowering the vitality and enabling the bacilli to develop and grow more readily.

(c) **Delirium tremens**, an incident in chronic alcoholism, results from the long-continued action of the poison. The condition was first accurately described early in the 19th century by Sutton, of Greenwich, who had numerous opportunities for studying the different forms among sailors. One of the most careful studies was made by Ware, of Boston. A spree in a temperate person, no matter how prolonged, is rarely if ever followed by delirium tremens; but in a habitual drinker a temporary excess may bring on an attack or it follows the sudden withdrawal of alcohol. An accident, a sudden shock, or an acute inflammation, particularly pneumonia, may determine the onset. It is especially apt to occur in drinkers admitted to hospitals for injuries, especially fractures, and, as this seems most likely to occur when alcohol is withdrawn, it is well to give such patients a moderate amount of alcohol. At the outset of the attack the patient is restless and depressed and sleeps badly; after a day or two the characteristic *delirium* sets in. The patient talks constantly and incoherently; he is incessantly in motion, and desires to go out and attend to some imaginary business. Hallucinations of sight and hearing develop. He sees objects in the room, such as rats or mice, and fancies that they are crawling over his body. The terror inspired by these imaginary objects is great and the patients need to be watched constantly, for in their delusions they may jump out of the window or escape. Auditory hallucinations are not so common, but the patient may complain of hearing animals or the threats of imaginary enemies. There is much muscular tremor; the tongue is covered with a thick white fur and is tremulous. The pulse is soft, rapid, and readily compressed. There is usually fever, but the temperature rarely registers above 102° or 103°. In fatal cases it may be higher. *Insomnia* is a constant feature. On the third or fourth day in favorable cases the restlessness abates, the patient sleeps, and improvement gradually sets in. The tremor persists for some days, the hallucinations gradually disappear, and the appetite returns. In more serious cases the insomnia persists, the delirium is incessant, the pulse becomes more frequent

and feeble, the tongue dry, the prostration extreme, and death results from heart-failure.

Some regard *mania à potu* as a distinct form in which the onset is sudden and the patients are very violent, but hallucinations and terror are rare.

There is a condition termed *acute hallucinosis*, in which auditory hallucinations are marked, orientation is retained, and the mental disturbances are fixed. Ideas of persecution are common. There are intermediate forms between this and the ordinary delirium tremens.

Diagnosis.—The clinical picture can scarcely be confounded with any other. Cases with fever may be mistaken for meningitis. The most common error is to overlook some local disease, such as pneumonia, or an injury, as a fractured rib, which in a chronic drinker may precipitate an attack of delirium tremens. In every instance a careful examination should be made, particularly of the lungs. It is to be remembered that in the severer forms, particularly the febrile cases, congestion of the bases of the lungs is by no means uncommon. Another point is that pneumonia of the apex may be accompanied by similar delirium.

Prognosis.—Recovery takes place in a large proportion of the cases in private practice. In hospital practice, particularly in large city hospitals to which debilitated patients are taken, the death-rate is higher. Gerhard stated that of 1,241 cases admitted to the Philadelphia Hospital 121 proved fatal. Recurrence is frequent, indeed, the rule, if the drinking is kept up.

Treatment.—*Acute* alcoholism rarely requires any special measures, as the patient sleeps off the effects of the debauch. In the case of profound alcoholic coma it may be advisable to wash out the stomach, and if collapse symptoms occur the limbs should be rubbed and hot applications made to the body. Should convulsions supervene, chloroform may be carefully administered. In the acute, violent alcoholic mania the hypodermic injection of apomorphia, one-eighth of a grain (0.008 gm.), is usually very effectual, causing nausea and vomiting, and rapid disappearance of the maniacal symptoms.

Chronic alcoholism is a condition very difficult to treat, and once fully established the habit is rarely abandoned. The most obstinate cases are those with marked hereditary tendency. Withdrawal of the alcohol is the first essential. This is most effectually accomplished by placing the patient in an institution, in which he can be carefully watched. The absence of temptation in institution life is of special advantage. For the sleeplessness the bromides or hyoscine may be employed. Quinine and strychnine in tonic doses may be given. Prolonged seclusion in a suitable institution is in reality the only effectual means of cure. When an hereditary tendency exists a lapse into the drinking habit is almost inevitable.

In *delirium tremens* the patient should be confined to bed and carefully watched night and day. The danger of escape is very great, as the patient imagines himself pursued by enemies or demons. Flint mentions the case of a man who escaped in his nightclothes and ran barefooted for fifteen miles on the frozen ground before he was overtaken. The patient should not be strapped in bed, as this aggravates the delirium; sometimes some form of restraint is advisable which should be as simple as possible; a sheet tied across the bed may be sufficient. This is certainly better than violent restraint by

attendants. Alcohol should always be withdrawn unless the pulse is feeble.

Delirium tremens is a disease which, in a large majority of cases, runs a course very slightly influenced by medicine. The indications for treatment are to procure sleep and to support the strength. In mild cases half a dram (2 gm.) of bromide of potassium with tincture of capsicum may be given every three hours. Chloral is often of great service (15 grains, 1 gm.) and may be given without hesitation. Good results sometimes follow the hypodermic use of hyoscine (gr. 1/100, 0.00065 gm.). Opium must be used cautiously. A special merit of Ware's work was the demonstration that with expectant treatment the percentage of recoveries was greater than with the indiscriminate use of sedatives, which had been in vogue for many years. When opium is indicated it should be given as morphia, hypodermically. The effect should be carefully watched, and, if after three or four quarter-grain doses have been given the patient is still restless and excited, it is best not to push it farther. Repeated doses of barbital (gr. x, 0.6 gm.) or phenobarbital (gr. i, 0.065 gm.) may be tried. Lambert advises ergotin hypodermically in both the acute and chronic alcoholism. With acidosis alkalies and water should be given freely. When fever is present the effects of a douche or bath may be tried, or wet packs. The large doses of digitalis formerly employed are not advisable. Lumbar puncture is sometimes useful.

Careful feeding is a most important element in the treatment of these patients. Milk and concentrated food should be given at stated intervals. If the pulse becomes rapid and shows sign of flagging, alcohol may be given in combination with the aromatic spirit of ammonia.

Methyl (Wood) Alcohol Poisoning.—Methyl alcohol is used extensively in trade but its importance as a toxic agent is due to its use as an adulterant in spirits for internal use and applications for external use, such as bay-rum, etc. It is not oxidized or excreted as rapidly as ethyl alcohol and is much more toxic. Poisoning usually results from drinking methyl alcohol but may result from external application or from inhalation. It has a selective toxic effect on the optic nerve and retina, resulting in a partial or complete blindness.

Symptoms.—These are much like those of ethyl alcohol with the addition of the injury to the optic nerve or retina. The coma due to wood alcohol is often deeper and of longer duration and delirium, nausea, vomiting and collapse are usually more marked. There may be marked dyspnoea and respiratory failure. Acidosis may be present, due partly to the production of formic acid. The outlook is serious if the coma is marked. In treatment the stomach should be washed and an ounce of Epsom salts given by the tube, the colon washed out and stimulation used as indicated. Alkaline treatment is advisable by mouth and rectum, and intravenous injection of saline solution. Lumbar puncture should be done.

II. OPIUM (MORPHIA, HEROIN) HABIT

Taken at first for various reasons, a craving for the drug is gradually engendered, and the habit acquired. The effects of the constant use of opium vary very much. In the East, where opium-smoking is almost as common as tobacco-smoking with us, the ill effects are, according to good observers, not

very striking. Taken as morphia and hypodermically, as is the rule, it is very injurious but a moderate amount may be taken for years without serious damage.

The habit is particularly prevalent among women and physicians who use the hypodermic syringe for the alleviation of pain, as in neuralgia or sciatica. The acquisition of the habit as a pure luxury is rare.

In the United States the use of *heroin* has greatly increased of recent years. In many cases the habit begins in youths below the age of twenty. The "neurotic" seems especially prone to acquire the habit. There is no evidence that prohibition has increased the morphia or heroin habit. The alcoholic as a rule does not take to these drugs. There is no evidence of the use of codein leading to a habit.

Symptoms.—The symptoms at first are slight and for months there may be no disturbance of health. There are exceptional cases in which for years excessive amounts have been taken without deterioration of the mental or bodily functions. As a rule, the dose necessary to obtain the desired sensation has gradually to be increased. As the effects wear off the victim experiences sensations of lassitude and mental depression, accompanied often with slight nausea and epigastric distress, or even recurring colic, which may be mistaken for appendicitis. The confirmed opium-eater usually has a sallow, pasty complexion, is emaciated, and becomes prematurely gray. He is restless, irritable, and unable to remain quiet for any time. Itching is a common symptom. The sleep is disturbed, the appetite and digestion are deranged, and except when directly under the influence of the drug the mental condition is one of depression. Occasionally there are profuse sweats, which may be preceded by chills. The pupils, except when under the direct influence of the drug, are dilated, sometimes unequal. In one case there was a persistent œdema of the legs without renal changes or anæmia to account for it. Persons addicted to morphia or heroin are inveterate liars, and no reliance whatever can be placed upon their statements. In many instances this is not confined to matters relating to the vice. In women the symptoms may be associated with those of pronounced hysteria or neurasthenia. The practice may be continued for an indefinite time, usually requiring increase in the dose until ultimately enormous quantities may be needed to obtain the desired effect. Finally a condition of asthenia is induced, in which the victim takes little or no food and dies from the extreme bodily debility. An increase in the dose is not always necessary, and there are *habitués* who reach the point of satisfaction with a daily amount of 2 or 3 grains of morphia, and who are able to carry on successfully for many years the ordinary business of life. They may remain in good physical condition, and indeed often look ruddy. The general effects of heroin addiction are less marked than those of morphinism.

Treatment.—This is extremely difficult, and can rarely be successfully carried out by the general practitioner. Isolation, systematic feeding, and gradual withdrawal of the drug are the essential elements. As a rule, the patients must be under control in an institution and should be in bed for the first ten days. It is best in a majority of cases to reduce the morphia gradually. The sufferings of the patients are usually very great, more particularly the abdominal pains, sometimes nausea and vomiting, and the distressing restlessness. Usually within a week or ten days the drug may be entirely withdrawn.

In all cases the pulse should be carefully watched and, if feeble, aromatic spirit of ammonia and digitalis should be given. For the extreme restlessness a hot bath is serviceable. The sleeplessness is the most distressing symptom, and various drugs may have to be resorted to, particularly hyosine and barbital and sometimes, if the insomnia persists, morphia itself.

It is essential to be certain that the patient has no means of obtaining morphia. Even under the favorable circumstances of seclusion in an institution and constant watching, patients may practise deception. After an apparent cure the patients are only too apt to lapse into the habit.

The condition is one which has become so common, and is so much on the increase, that physicians should exercise the utmost caution in prescribing morphia, particularly to female patients and to those with chronic diseases. Under no circumstances should a patient be allowed to use the hypodermic syringe.

III. COCAINISM

The addiction may be acquired through curiosity or by the use of cocaine to relieve fatigue. Habitues seem to take pleasure in teaching the habit to others. The use of cocaine solutions in sprays may be responsible. The subjects are often of the "neurotic" class and the habit is frequently acquired by minors. The drug is usually taken by snuffing, sometimes hypodermically. As a rule the dose is increased rapidly.

Symptoms.—These are much like those of morphinism but the effects of the drug are of shorter duration and are followed by marked depression and weakness. Sometimes there are temporary periods of marked exhilaration. Later the general health suffers: weakness, digestive disturbances, tremor, disturbances of sensation and mental features appear. If present, hallucinations are often associated with the skin and the patient imagines that insects cover him or are in the skin. The delusions are often of persecution and may lead to criminal acts. The moral degradation is often greater than from morphinism and the chance of ending the habit is less. The treatment is along the same general lines as in morphinism.

IV. LEAD POISONING

(Plumbism, Saturnism)

Etiology.—The disease is widespread, particularly in the lead industries and among plumbers, painters, and glaziers. In 1923 there were 55 deaths in England and Wales from occupational lead poisoning. In the United States it is not easy to get accurate statistics. In the registration area there were 119 deaths in 1920. Alice Hamilton reports 358 cases with 16 deaths in 23 white lead factories during the 16 months to May 1, 1911. The metal is introduced into the system in many forms. Miners usually escape, but those engaged in the smelting of lead-ores are often attacked. Animals in the neighborhood of smelting furnaces have suffered with the disease, and even the birds that feed on the berries in the neighborhood may be affected. Men

engaged in the white-lead factories are particularly prone to plumbism. Accidental poisoning may come in many ways; most commonly by drinking water which has passed through lead pipes or been stored in lead-lined cisterns. Wines and cider which contain acids quickly become contaminated in contact with lead. It was the frequency of colic in certain of the cider districts of Devonshire which gave the name of Devonshire colic, as the frequency of it in Poitou gave the name *colica Pictonum*. Among the innumerable sources of accidental poisoning may be mentioned milk, various sorts of beverages, cosmetics containing lead, hair dyes, false teeth, and thread. A few cases have followed the retention of lead bullets in gun-shot wounds. Given medicinally, lead may cause poisoning. It has followed the use of Emplastrum Diachylon to produce abortion, and there is a case reported in an infant from the application of lead-water on the mother's nipples. One grain every three hours for three days, and two grains every three hours for one day, have caused signs of poisoning. A serious outbreak of lead-poisoning occurred in Philadelphia, owing to adulteration of a baking-powder with chromate of lead, used to give a yellow tint to cakes. Poisoning has followed the use of snuff to which chromate of lead had been added.

All ages are attacked, but children are relatively less liable. The largest number of cases occur between thirty and forty. According to Oliver, females are more susceptible than males. They are much more quickly brought under its influence, and in an epidemic in which a thousand cases were involved the proportion of females to males was four to one. Miscarriage is common, and it is rare for a woman working in lead to carry a child to term. It also destroys the reproductive power in man.

The lead gains entrance through the lungs, the digestive organs, or the skin. Through the lungs it is freely absorbed. The chief channel, according to Oliver, is the digestive system. It is carried in the body as a phosphate and stored in the calcareous parts of the bones. An excess of calcium favors harmless storage in the body and a deficiency favors excretion. It is rapidly eliminated by the gastro-intestinal tract, kidneys and skin. The susceptibility is remarkably varied. The symptoms may be manifest within a month of exposure. On the other hand, Tanquerel (des Planches) met with a case in a man who had been a lead-worker for fifty-two years. E. R. Hayhurst examined 100 painters, not one of whom had symptoms of acute plumbism, but 70 showed in varying degrees symptoms, signs, or after-effects of chronic plumbism; a lead-line on the gums was present in 19 cases. Tetra-ethyl lead causes severe poisoning, affecting the nervous system particularly. It is rapidly absorbed through the skin.

Morbid Anatomy.—Small quantities of lead occur in the body in health. Of 264 deaths in subjects of plumbism 32 were due to an encephalopathy, 43 to nephritis, 47 to cerebral hæmorrhage, 43 to paralysis, 44 to lead poisoning, 38 to tuberculosis, and 40 to various maladies, pneumonia, heart disease, aneurism, etc. (Legge).

In chronic poisoning lead is found in the various organs. The affected muscles are yellow, fatty, and fibroid. The nerves present the features of a peripheral degenerative neuritis. In the primary atrophic form the ganglion cells of the anterior horns are implicated. In the acute fatal cases there may be intense entero-colitis.

Symptoms.—**ACUTE FORM.**—We do not refer here to the accidental or suicidal cases, which present vomiting, pain in the abdomen, and collapse symptoms. There are manifestations which follow a short time after exposure and set in acutely. There may be severe colic with constipation or diarrhœa with enteritis and in addition a rapidly developing anæmia. Acute neuritis has been described, and convulsions, epilepsy, and a delirium, which may be not unlike that produced by alcohol. There are cases in which the gastrointestinal symptoms are intense and rapidly prove fatal. These acute forms occur more frequently in persons recently exposed, and more often in winter than in summer. Da Costa reported the onset of hemiplegia after three days' exposure to lead.

CHRONIC POISONING.—(a) *Blood Changes.*—A moderate grade of anæmia, the so-called saturnine cachexia, is usually present. There is marked pallor perhaps due to vaso-constriction. The corpuscles do not often fall below 50 per cent. Many of the red cells show a remarkable granular, basophilic degeneration when stained with Jenner's stain or polychrome methylene blue. Grawitz first demonstrated their presence in pernicious anæmia, and Pepper (tertius) and White showed that they were constantly present in lead-poisoning. Such granulations are found in the blood in a great variety of conditions, even in normal blood, but they are most numerous in lead-poisoning, in which their occurrence in large numbers is of value in diagnosis. Cadwalader has shown the constant presence of nucleated red blood corpuscles even when the anæmia is of very slight grade.

(b) *The blue line on the gums* is a valuable indication, but is not invariably present. Two lines must be distinguished: one, at the margin between the gums and teeth, is on, not in the gums, and is removed by cleansing the teeth. The other is the characteristic blue-black line at the margin of the gum. The color is not uniform, but being in the papillæ of the gums the line is, as seen with a magnifying-glass, interrupted. The lead is absorbed and converted in the tissues into a black sulphide by the action of sulphuretted hydrogen from the tartar of the teeth. The line may form in a few days after exposure (Oliver) and disappear within a few weeks, or may persist for months. Philipson noted the occurrence of a black line in miners, due to the deposition of carbon, and bismuth may give a line much like lead.

The most important symptoms of chronic poisoning are colic, palsy, and the encephalopathy. Of these, the colic is the most frequent. Of Tanquerel's cases, there were 1,217 of colic, 101 of paralysis, and 72 of encephalopathy.

(c) *Colic is the most common symptom of chronic lead-poisoning.* It is often preceded by gastric or intestinal symptoms, particularly constipation. The pain is over the whole abdomen. The colic is usually paroxysmal and relieved by pressure. There is often a dull, heavy pain between the paroxysms. There may be vomiting. During the attack, as Riegel noted, the pulse is increased in tension and the heart's action is retarded. Attacks of pain with acute diarrhœa may recur for weeks or even for three or four years.

Certain of the cases with colic may present the features of an acute intra-abdominal inflammatory condition. A patient may be admitted with a diagnosis of appendicitis or intestinal obstruction. Localized pain, slight fever, and moderate leucocytosis may be present. The history, the blue line on the gums, and the blood changes are of importance in diagnosis.

(d) *Lead-palsy*.—This is rarely a primary manifestation. Among 54 cases of lead-poisoning treated in the J. H. H. and dispensary there were 30 cases of lead-paralysis (H. M. Thomas). The upper limbs are most frequently affected. In 26 cases the arms alone were affected, and 18 of these showed the typical double wrist-drop. In 7 the right arm alone was involved, and in one the left. In 4 cases both arms and legs were attacked. The onset may be acute, subacute, or chronic. It usually occurs without fever. In its distribution it may be partial, limited to a muscle or to certain muscle groups, or generalized, involving in a short time the muscles of the extremities and the trunk. The muscles most used are often attacked. Madame Déjerine-Klumpke described the following *localized forms*: (1) *Antebrachial type*, paralysis of the extensors of the fingers and of the wrist. In this the musculospiral nerve is involved, causing the characteristic wrist-drop. The supinator longus usually escapes. In the long-continued flexion of the carpus there may be slight displacement backward of the bones, with distention of the synovial sheaths, so that there is a prominent swelling over the wrist known as Gruebler's tumor. (2) *Brachial type*, which involves the deltoid, the biceps, the brachialis anticus, and the supinator longus, rarely the pectorals. The atrophy is of the scapulo-humeral form. It is bilateral, and sometimes follows the first form, but it may be primary. (3) The Aran-Duchenne type, in which the small muscles of the hand and of the thenar and hypothenar eminences are involved. The atrophy is marked, and may be the first manifestation. Möbius has shown that this form is particularly marked in tailors. (4) The peroneal type. According to Tanquerel, the lower limbs are involved in the proportion of 13 to 100 of the upper limbs. The lateral peroneal muscles, the extensor communis of the toes, and the extensor proprius of the big toe are involved, producing the *steppage gait*. (5) Laryngeal form. Adductor paralysis was noted by Morell Mackenzie and others in lead-palsy.

Generalized Palsies.—There may be a slow, chronic paralysis, gradually involving the extremities, beginning with the classical picture of wrist-drop. More frequently there is a rapid generalization, producing complete paralysis in all the muscles of the parts in a few days. It may pursue a course like an ascending paralysis, associated with rapid wasting of all four limbs but such cases are rare. Death has occurred by involvement of the diaphragm. In one patient with generalized paralysis this began in the legs after but two weeks' work as an enameler. It spread rapidly, so that in a little over a week he was bedridden, and on admission to the hospital nearly every muscle below the neck was involved. The diaphragm was completely paralyzed. He was walking when he left the hospital, though there was still some weakness. Déjerine-Klumpke also recognized a febrile form of general paralysis which may closely resemble the subacute spinal paralysis of Duchenne.

There is also a primary saturnine muscular atrophy in which the weakness and wasting come on together. It is this form, according to Gowers, which most frequently assumes the Aran-Duchenne type.

The electrical reactions are those of lesions of the lower motor segment. The reaction of degeneration in its different grades may be present, depending upon the severity. Usually with the onset of the paralysis there are pains in the legs and joints. Sensation may, however, be unaffected.

(e) *Cerebral Symptoms*.—Headache is common and there may be marked

depression; delusions and maniacal excitement may follow. In other cases transient delirium, attacks of unconsciousness and convulsions result. Optic neuritis or neuro-retinitis may occur. Hysterical symptoms occasionally occur in girls. Convulsions are not uncommon, and in an adult the possibility of lead-poisoning should always be considered. True epilepsy may follow the convulsions. An acute delirium may occur with hallucinations. The patients may have trance-like attacks, which follow or alternate with convulsions. A few cases of lead encephalopathy finally drift into lunatic asylums. Tremor, especially of the lips, eyelids, tongue and fingers, is a common manifestation.

(f) Arterio-sclerosis.—Lead-workers are notoriously subject to arterio-sclerosis with contracted kidneys and hypertrophy of the heart. Some show distinct gouty deposits but in the United States acute gout in lead-workers is rare.

Diagnosis.—In marked cases this offers no difficulty. The occupation is always of aid if it is one in which lead is handled. It is in the cases of "accidental" poisoning that particular difficulty arises. In women the use of certain face powders and applications is not an uncommon cause and should be kept in mind. A careful study of the blood and a search for lead in the urine are important. Excretion of lead may continue long after ingestion has ceased.

Prognosis.—In the minor manifestations this is good. According to Gowers, the outlook is bad in the primary atrophic form of paralysis. Convulsions are, as a rule, serious, and the mental symptoms which succeed may be permanent. Occasionally the wrist-drop persists. Encephalopathy always has a grave prognosis. With vascular or renal disease, the prognosis depends largely on the degree of damage in these systems.

Treatment.—Prophylactic measures should be taken at all lead-works, but, unless employees are careful, poisoning is apt to occur even under favorable conditions. Cleanliness of the hands and of the finger-nails, frequent bathing, and the use of respirators when necessary should be insisted upon. The patient should be in bed on liquid and soft diet; water should be taken freely and the bowels kept open. This last is difficult to accomplish; mineral oil in full doses and sodium or magnesium sulphate (one ounce once or twice a day) should be given. Smaller doses of the salines (3i-ii, 4-8 gm.) several times a day may be more effectual. Belladonna or atropine in full doses often seems to be of advantage. Benzyl benzoate is sometimes useful. In acute cases it is well to try and hold the lead in the bones and for this calcium should be given freely in milk, two quarts a day, and as calcium lactate 60 grains (4 gm.) daily. After the acute features are over a diet low in calcium should be given (meat, potatoes, rice, macaroni, milk-free bread, sugar, apples, bananas; avoiding milk, eggs and green vegetables). Ammonium chloride 3 ii-iii (8-12 gm.) a day, sodium bicarbonate gr. 30-60 (2-4 gm.) a day or dilute phosphoric acid in doses of 3 v (20 c. c.) may be given to aid the excretion. Iodide can be given in from 5- to 10-grain (0.3-0.6 gm.) doses three times a day unless the poisoning is severe. For the colic hot applications and, if severe, morphia may be used. For the anæmia iron should be used. In acute cases it is well not to give iodide, as the liberation of the lead deposited in the tissues may increase the severity of the symptoms. For the local palsies massage and the constant current should be used. After recovery the need of change in occupation should be considered.

The intravenous administration of sodium thiosulphate (0.5 gm. being the average dose) daily for four days and afterwards every other day for as long as necessary is advised. It is supposed that the drug renders soluble the lead bound by a protein radicle.

V. BRASS AND ZINC POISONING

Brass, a compound of copper and zinc, is not harmful itself; poisoning is due to the inhalation of zinc oxide fumes. The cause is not clear; an anaphylactic reaction due to destruction of protein in the respiratory tract is suggested. Brass polishers and those exposed to the dust have the hair stained somewhat green and there is often a slight greenish deposit in the teeth and gums. It is said that there may be a green tint to the perspiration, even after a thorough bath.

The dust may cause an itching of the skin, the so-called "brass itch." The fumes from molten brass cause peculiar symptoms, the so-called "brass-workers' ague," "metal fume fever," "smelters' shakes" and "zinc chills." The symptoms are an acute chill, which comes on some hours after exposure to the molten metal, sweating and a feeling of nausea; there may be vomiting, great thirst, a rapid, feeble pulse, a rise of temperature, leucocytosis, and in the course of a couple of hours very profuse sweating. The entire attack may last for six or eight hours, or the patient may be ill for a day. Many of our patients used to say that they were more liable to it on Monday, after Sunday's rest. A large percentage of the workers are susceptible. It does not seem to impair the health very much, yet it is notorious how short-lived are the brass-workers in Birmingham. A decrease in vital capacity has been found. The malady is widespread among the workers in zinc in the United States.

In treatment an emetic and a brisk purge may give relief. The drinking of milk and taking of sodium bicarbonate are advised.

VI. ARSENICAL POISONING

Acute poisoning by arsenic is common, particularly by Paris green and such mixtures as "Rough on Rats," which are used to destroy vermin and insects. The chief symptoms are intense pain in the stomach, vomiting, and, later, colic, with diarrhoea and tenesmus; occasionally the symptoms are those of collapse. If recovery takes place, paralysis may follow. The treatment is similar to that of other irritant poisons—rapid removal with the stomach tube, the promotion of vomiting and the use of milk and eggs. Moist ferric hydroxide (half an ounce of Tct. ferri chloridi in a glass of water and add magnesia to excess) should be given freely. Morphia should be given for pain and stimulation used for collapse.

Toxic effects from the arsenobenzol compounds are not infrequent. Among them are: (1) Dermatoses of various kinds. Erythema is not uncommon and its appearance is a signal to stop the therapy. Purpura and ecchymoses occur. (2) Encephalitis hæmorrhagica with which purpura may be asso-

ciated. (3) Injury to the liver cells of varying grade, with jaundice, toxæmia and possibly rapid atrophy. (4) A severe anæmia with the features of aplastic anæmia. The coagulation time of the blood may be prolonged. (5) Attacks of marked vaso-motor disturbance with low blood pressure. (6) Symptoms described as "anaphylactoid" or "nitritoid crisis" in which there are sudden dyspnoea, cyanosis, dilatation of the pupils, local œdema and erythematous or urticarial eruptions. The blood pressure may be low. The injection of epinephrine is indicated (15 min., 1 c. c. of a 1-1000 solution).

Arseniuretted hydrogen poisoning has occurred in submarines and from the gas being given off from "ferro-silicon." There is a special toxic action on the liver and kidneys. Symptoms appear in a few hours, nausea, vomiting, and headache; jaundice, hæmaturia and anæmia follow. The anæmia may be severe. Delirium followed by coma may result in death.

Chronic Arsenical Poisoning.—Arsenic is used extensively in the arts, particularly in the manufacture of colored papers, artificial flowers, and in many fabrics. The glazed green and red papers used in kindergartens also contain arsenic. It is present in many wall-papers and carpets. Much attention has been paid to this question, as instances of poisoning have been thought to depend upon wall-papers and household fabrics. The arsenic compounds may be in the form of solid particles detached from the paper or as gaseous volatile bodies formed from arsenical organic matter by the action of several moulds. In moisture, and at a temperature of from 60° to 95° F., a volatile compound is set free, probably "an organic derivative of arsenic pentoxide" (Sanger). The chronic poisoning from fabrics and wall-papers may be due to the ingestion of minute continued doses of this derivative. Contaminated glucose, used in manufacturing beer, caused a widespread epidemic of poisoning at Manchester. The associated presence of selenium compounds may have played a part in the production of the poisoning (Tunncliffe and Rosenheim). Arsenic is eliminated in all the secretions, and has been found in the milk. J. J. Putnam showed that it is not uncommon to find traces of arsenic in the urine of many persons in apparent health. The effects of moderate quantities of arsenic are not infrequently seen in medical practice. Flushing and hyperæmia of the skin, puffiness of the eyelids or above the eyebrows, nausea, vomiting, and diarrhoea are the most common symptoms. Redness and sometimes bleeding of the gums and salivation occur. In the protracted administration of arsenic patients may complain of numbness and tingling in the fingers. Cutaneous *pigmentation* and keratosis are very characteristic, and, as a late rare sequence of the latter, epithelioma. Perforation of the nasal septum may occur. Care should be exercised to avoid the therapeutic overdosage of arsenic, especially in chorea.

In the Manchester epidemic nearly all cases presented signs of neuritis and lesions of the skin. In some the sensory disturbances predominated, in others the motor, the individuals being unable to walk or to use their hands. In a certain number there was muscular incoördination, resembling that of tabes dorsalis. Rapid muscular atrophy characterized some cases. In not a few a condition of erythromelalgia was present. Occasionally a catarrh of the respiratory and alimentary tracts was the chief feature. Pigmentation, keratosis, and herpes were the most characteristic cutaneous manifestations.

Arsenical paralysis has the same characteristics as lead-palsy, but the legs

are more affected than the arms, particularly the extensors and peroneal group, so that the patient has the characteristic *steppage* gait of peripheral neuritis. The electrical reaction in the muscles may be disturbed before there is any loss of power, and when the patient is asked to extend the wrist fully and to spread the fingers slight weakness may be detected early.

Treatment.—Active elimination by the bowels and kidneys is advisable and the treatment of special conditions as indicated. The use of sodium thio-sulphate (0.5 gm.) intravenously is advised as in lead poisoning.

VII. MERCURIAL POISONING

Acute Poisoning.—This is comparatively common in mild forms from the use of mercury compounds in therapy, especially calomel by mouth and ointment by inunctions. The commonest results are salivation and stomatitis. There is usually a curious foul metallic odor to the breath for some days before stomatitis appears. This should be watched for as prompt treatment may prevent later manifestations. The patient may complain of a metallic taste, tenderness on chewing or bringing the teeth forcibly together, or of tenderness of the gums. The secretion of saliva increases, the gums swell, ulceration may follow, the teeth may be loosened and fall out, and in severe cases extensive necrosis may result which may involve the carotid artery.

The most acute form results from the taking of *bichloride of mercury*, sometimes accidentally, often for suicide. The symptoms usually appear in a short time. Corrosive effects on the mouth or throat may give pain. Vomiting with abdominal pain, frequent bowel movements often containing blood, and sometimes collapse follow promptly. Severe stomatitis usually appears in a short time and the signs of colitis usually increase. The movements are bloody and may contain shreds of necrotic tissue. *Nephritis*, usually of a severe form, results also, the urine being very scanty or complete suppression resulting. In some cases the signs of colitis and nephritis may be delayed for some days. The course is very variable; the nephritic features being important in prognosis. There may be almost complete suppression for several days followed by recovery. Edema is not common but there is marked retention of the nitrogenous substances in the blood, which is an important aid in prognosis. Patients may do well for some days and then renal insufficiency becomes more marked. If there is any doubt as to the diagnosis the vomitus, urine and stools should be examined for mercury.

Treatment.—Care should be taken in the administration of mercury to recognize the earliest signs of salivation and stop the drug. Patients should be told which signs to watch for and instructed to report. Any form of mercury used for purgation should be followed by a saline. For stomatitis the diet may have to be liquid, water should be given freely and the bowels kept open by salines and enemata. Mouth washes should be used freely and often, such as potassium chlorate solution, hydrogen peroxide solution (1 to 4) or potassium permanganate (2 per cent.). The gums should be painted daily with silver nitrate solution (5 per cent.). Atropine is sufficient dosage usually controls the salivation. In patients taking mercury for syphilis particular care should be given to the state of the gums and teeth.

In *bichloride* poisoning, the whites of several eggs should be given at once and the stomach emptied by the tube, after which one ounce of Epsom salts is given through the tube. An *enema* should then be given and the colon emptied. Saline solution (1,000 c. c.) should be given intravenously. The stomach should be washed and the colon irrigated twice a day, as mercury is excreted by the gastric and intestinal mucous membrane. A hot pack should be given twice a day. It is important to give fluid freely. Milk is given every two hours (8 ounces) and alternately every two hours 8 ounces of the following (Lambert and Patterson): Potassium bitartrate and cane sugar, each 3 ii (8 gm.), lactose 3 i (30 gm.), lemon juice 3 ii (60 c. c.) and water to one quart (1,000 c. c.). As much alkaline solution as possible is given by the bowel (potassium citrate gr. xv, 1 gm.) to the pint (500 c. c.) either by the drop method or 250 c. c. every two hours. Saline solution should be given subcutaneously or intramuscularly. The administration of fluid should be kept up through the twenty-four hours, the patient being waked if necessary.

Good results are reported from the intravenous administration of sodium thiosulphate (0.5 gm.) as in lead poisoning. In case of poisoning by absorption from the vagina, douches of 5 per cent. sodium thiosulphate solution should be used.

Chronic Poisoning.—This occurs chiefly among workers with the metal (in making instruments, electric bulbs, and mirrors), workers in furs and makers of hats in which nitrate of mercury is used. There have been cases due to the vapor and also from long *continued medicinal use*, as *bichloride vaginal douches*. It is occasionally a sequel of acute poisoning. The *local features* include stomatitis and salivation, marked fetor of the breath, an extreme condition of mouth infection, sometimes a blue line on the gums, *dyspepsia*, colitis, which may be ulcerative, and nephritis. The *nervous system* manifestations are important; tremors are common, usually fine and involving the tongue, face, arms and hands, and even the trunk and legs. Psychical changes may occur and general weakness, loss of weight and anæmia. If there is any doubt of the diagnosis, mercury should be searched for in the stools. In *treatment*, the patient should be removed from exposure to mercury; elimination aided by giving water freely and keeping the bowels open by *salines* and *enemata*; and necessary symptomatic measures used.

VIII. FOOD POISONING

There may be "death in the pot" from many causes. Food poisons may be *endogenous* or *exogenous*. Those articles in which the poison is of endogenous origin can scarcely be designated as foods. The poisonous mushroom, for example, is often mistaken for the edible form. The former is injurious because it normally contains a highly poisonous *alkaloid, muscarine*. Certain fish also produce normal physiological but toxic products. When eaten by mistake, as frequently occurs in the West Indies and Japan, these fish may cause poisonous symptoms. The exogenous origin of food poisons is by far the commonest. Under this head come those foods which are rendered poisonous by accidental contamination from outside sources. This may be from metal containers or the food may contain specific organisms, as of tuberculosis

or trichinosis; milk and other foods may become infected with typhoid bacilli, and so convey the disease.

Animals (or insects, as bees) may feed on substances which cause their flesh or products to be poisonous to man. The grains used as food may be infected with fungi and cause epidemics of ergotism, etc. Foods of all sorts may become contaminated with the bacteria of putrefaction, the products of which may be highly poisonous.

The term "ptomaine poisoning" has been popularized to such an extent that it is used synonymously with food poisoning but true ptomaine poisoning is very rare and the use of the term should be stopped. The term *ptomaine* was introduced by the Italian chemist, Selmi, to designate basic alkaloidal products formed in putrefaction. Mytilotoxin, found in poisonous mussels, is of this class, and is by far the most poisonous of the known ptomaines.

Among the more common forms are the following:

Poisoning from Fungi.—Poisonous fungi are eaten in error for edible mushrooms. The most poisonous varieties are the *Aminita muscaria* and *phalloides*. The former contains muscarine, and the symptoms usually appear within an hour after ingestion. They are largely gastro-intestinal, salivation, vomiting, pain and diarrhoea with collapse, sweating and delirium. The treatment consists in promoting free vomiting or washing out the stomach, washing out the colon, giving atropine freely and general stimulation. The *A. phalloides* contains a toxin which produces degeneration in the liver and kidney especially. The symptoms do not appear for some days. There are vomiting, diarrhoea, marked prostration, jaundice and suppression of urine. Death usually occurs in a few days. The treatment consists in free elimination and symptomatic measures.

Meat Poisoning.—Outbreaks of disease due to poisons of bacterial origin or to chemical changes are not uncommon.

(a) *Acute Epidemic Food Poisoning.*—The organisms causing this belong to the "Salmonella" group and those most often responsible are *B. aertrycke* and *B. gaertner*. The former is represented by various strains. The identification of these organisms depends on their sugar reactions and on specific serum reactions. The infection is usually carried by meat, especially pork. The incubation period varies from a few hours to 3 or 4 days. The greater the amount of preformed toxin, the shorter the incubation. The onset may be with a chill followed by fever or the temperature may be subnormal. Vomiting, abdominal pain and frequent offensive stools, sometimes bloody, follow, frequently with severe muscular pains and marked collapse. Skin rashes, erythema, urticaria and even purpura are not uncommon. Individuals react very differently; some have slight symptoms while in others death may result in twenty-four hours. Some cases of paratyphoid fever B have a close resemblance to this group and there may be a double infection. The diagnosis is usually clear from the clinical picture but metallic poisoning and acute dysentery may have similar features. The organism may be isolated from the stools, rarely from the blood and the serum reactions are diagnostic. The possibility of carriers must be kept in mind. In treatment, absolute rest, little food by mouth for a day (albumen water only), aerated water, hot applications to the abdomen and colon irrigations are important. Morphia hypodermically (gr. $\frac{1}{4}$, 0.016 gm.) is often useful. Bismuth and soda may be

given by mouth. In case of collapse, heat, saline injections and stimulation should be used.

(b) The question of *chronic* bacterial food poisoning is an obscure one. In case of persistent infection by a carrier such a condition may occur. The symptoms are those of chronic gastro-intestinal disturbance, perhaps colitis. Stool cultures and serum tests are essential for diagnosis.

(c) Meat poisoning associated with putrefaction. Here alterations of appearance, of smell and taste are usually present. The products are those of protein hydrolysis, various aromatic compounds, but particularly putrescine, cadaverine and sepsin. How far these bodies are responsible for the symptoms, how far they are due to infection with associated organisms, particularly colon bacilli, has not been definitely settled. Cases of food poisoning have been reported as due to proteus and its toxins. This organism was the cause of a severe outbreak due to eating potato salad.

Botulism (Allantiasis).—Poisoning due to the toxins of the *Bacillus botulinus*. Kuner, the Swabian physician and poet, described "sausage poisoning" in 1817. The organism was found by Van Ermengen in a ham, the eating of which caused 50 cases of botulism. There are various strains, and the organism is widely distributed in the soil. Formerly regarded as exclusively a form of meat poisoning, Dickson and his associates showed that the toxin may be formed in vegetable products, especially when "home-canned." Botulism is a true intoxication, the toxin being formed in the food and absorbed in the gastro-intestinal tract. It is destroyed by heating to the boiling point. Instances of poisoning seem to be increasing in the United States, the majority being caused by canned vegetables and fruits. The presence of bubbles of gas, a rancid odor and a softened appearance of the solid parts are suggestive of *B. botulinus* in canned materials. Uncooked or freshly cooked vegetables or fruits do not contain the toxin. The pathological lesions are marked thrombus formation both in the arteries and veins with hyperæmia and hæmorrhages in the meninges and central nervous system. There is an absence of inflammatory reaction. Edmunds holds that the peripheral changes are important, that it is a "curare-like" reaction, not necessarily complete, a paralysis of the motor nerve endings. He states that the nuclei most affected do not give the most marked clinical findings. The results are motor, not sensory.

Symptoms.—The onset is from 4 to 48 hours (usually 12 to 24) after ingestion of the toxin. There are weakness, dizziness, disturbance in vision, diplopia, ptosis, paralysees of the eye muscles, and difficulty in swallowing and respiration. Vertigo and incoördination are common. Cranial nerve paralysees are always present; all the cranial nerves except the first and second have been involved. Dryness of the mouth and throat and constriction of the throat with difficulty in speaking and swallowing follow. There is no headache or sensory disturbance. There may be retention of urine and occasional paralysees of the arms and legs. The deep reflexes are not altered. There are retention of food in the stomach and obstinate constipation. In the later stages bulbar symptoms are common, rapid respiration with dyspnœa and a slow pulse. There is no fever. Death occurs in from 1 to 8 days from cardiac or respiratory failure. As in other varieties of food poisoning there are grades of severity—mild or abortive cases may be recognized only by the

association with more severe forms. The mortality in 529 cases was 67.5 per cent. In *diagnosis* the evidence of food poisoning from a common source is important but the onset of symptoms varies and the victims may be widely scattered before symptoms appear. The cranial nerve paralyses seem to be a constant feature. Epidemic encephalitis may give difficulty, in which the history is perhaps the greatest aid. There are special methods of diagnosis by feeding suspected food material to chickens, susceptible to the A strain, but not to B, and its intraperitoneal injection into mice. Individual *prophylaxis* lies in the avoidance of suspicious canned fruit and the various forms of specially prepared potted meat preparations. In *treatment* the stomach should be promptly washed out, a purgative given and the colon irrigated; water should be given freely. Artificial respiration should be kept up as long as possible. The use of the antitoxin depends on early diagnosis; it may be useful up to 24 hours after ingestion.

Certain game birds, particularly the grouse, are poisonous in special districts and at certain seasons. It is interesting to note that mutton and lamb have thus far not been implicated as a cause of food poisoning.

Poisoning by Milk Products.—(a) The poisonous effects which follow the drinking of milk infected with saprophytic bacteria are considered in the section on the diarrhoea of infants.

(b) *Cheese Poisoning.*—Various milk products, ice cream, custard, and cheese, may prove highly poisonous. In one epidemic Vaughan and Novy isolated from cheese a substance belonging to the poisonous albumins, and in an extensive ice-cream epidemic Vaughan and Perkins found in the ice cream a highly pathogenic bacillus, but its toxin has not been separated. The symptoms are those of acute gastro-intestinal irritation.

Poisoning by Shell-fish and Fish.—(a) *Mussel Poisoning.*—Brieger separated a ptomaine—mytilotoxin—which exists chiefly in the liver of the mussel. Schmidtman and Cameron showed that the mussel from the open sea only becomes poisonous when placed in filthy waters.

Dangerous, even fatal, effects may follow the eating of either raw or cooked mussels. The symptoms are those of an acute poisoning with profound action on the nervous system, and without gastro-intestinal manifestations. There are numbness and coldness, no fever, dilated pupils, and rapid pulse; death occurs sometimes within two hours with collapse symptoms. In an epidemic at Wilhelmshafen, Germany, in 1885, nineteen persons were attacked, four of whom died. Salkowski and Brieger isolated the *mytilotoxin* from the mussels. Poisoning occasionally follows the eating of oysters which are stale or decomposed. The symptoms are usually gastro-intestinal.

(b) *Fish Poisoning.*—There are two distinct varieties: in one the poison is a physiological product of certain glands of the fish, in the other it is a product of bacterial growth. The salted sturgeon used in parts of Russia has proved fatal to large numbers of persons. In China and Japan various species of the *tetrodon* are toxic, sometimes causing death within an hour, with symptoms of intense disturbance of the nervous system. Canned fish may cause poisoning by infection before the canning; after the cans are opened, canned fish is very liable to bacterial infection.

Grain and Vegetable Food Poisoning.—(a) *Ergotism.*—The prolonged use of meal made from grain contaminated by the ergot fungus (*Claviceps*

purpurea) cause a series of symptoms known as ergotism, epidemics of which have prevailed in parts of Europe. In acute ergotism there is acute enteritis with nervous system manifestations. Two forms of chronic ergotism are described—the one, *gangrenous*, is believed to be due to sphacelinic acid, the other, *convulsive* or *spasmodic*, is due to cornutin. In the former gangrene affects the extremities—usually the toes and fingers, less commonly the ears and nose. Preceding the gangrene there are usually anæsthesia, tingling, pains, spasmodic movements of the muscles, and blood stasis in certain vascular territories.

The nervous manifestations are very remarkable. After a prodromal stage of ten to fourteen days, in which the patient complains of weakness, headache, and tingling sensations in different parts of the body, perhaps accompanied with slight fever, symptoms of spasm develop, producing cramps in the muscles and contractures. The arms are flexed and the legs and toes extended. These spasms may last from a few hours to many days and relapses are frequent. In severer cases convulsive seizures develop and the patient may die in them. Mental symptoms are common, manifested sometimes in a preliminary delirium, but more commonly as melancholia or dementia. Posterior spinal sclerosis occurs in some cases. In a group of 29 cases (Tuczek and Siemens) 9 died at various periods after the infection, and four post mortems showed degeneration of the posterior columns. A condition similar to tabes dorsalis is gradually produced by this slow degeneration in the spinal cord.

(b) *Lathyrism* (*Lupinosis*).—An affection produced by the use of meal from certain vetches, chiefly *Lathyrus sativus* and *L. cicera*, popularly known as the chick-pea. The grains are usually powdered and mixed with the meal from other cereals in the preparation of bread. As early as the seventeenth century it was noticed that the use of flour with which the seeds of the *Lathyrus* were mixed caused stiffness of the legs. The subject did not attract much attention before the studies of James Irving, in India, who, between 1859 and 1868 in several communications, described a form of spastic paraplegia in certain regions of India due to the use of meal made from the *Lathyrus* seeds. It also produces a spastic paraplegia in animals. The Italian observers describe a similar form of paraplegia, and it has been observed in Algiers. The condition is that of a spastic paralysis, involving chiefly the legs, which may proceed to complete paraplegia. The arms are rarely, if ever, affected. It is evidently a slow lateral sclerosis.

(c) *Potato-poisoning*.—Potatoes contain normally a very small amount (about 0.06 per cent.) of the poisonous principle solanin, and, under certain circumstances, the poison may be in amounts sufficient to cause grave disturbance. The increase is due to the action of at least two species of bacteria, *B. solaniferum non-colorabile* and *B. solaniferum colorabile*, and occurs in those tubers which, during growth, have lain partially exposed above ground, and in those which, during storage, have become well sprouted. In one outbreak fifty-six persons, after eating sprouted potatoes, were seized with chills, fever, headache, vomiting, diarrhoea, colic, and great prostration. Many were jaundiced and several collapsed, but all recovered. Samples of the remaining potatoes yielded 0.38 per cent. of solanin, indicating that a full portion must have contained about 5 grains.

(d) The "Vomiting Sickness" of Jamaica is due to poisoning by spoiled

ackees—the fruit of *Blighia sapida*. Children are especially susceptible; the main features are vomiting, convulsions and coma; the average duration is twelve hours; the death rate is 85 per cent. (Scott).

Anaphylaxis.—Some individuals have a hyper-susceptibility to certain proteins and this may result in very diverse phenomena. The sensitization may be natural or acquired and may be due to absorption from the digestive tract. The features are very variable; in an infant susceptible to cow's milk there may be vomiting, diarrhoea, urticaria or erythema, dyspnoea and prostration with a weak and rapid pulse. Angio-neurotic oedema results in some individuals. Some chronic skin affections, such as eczema, perhaps psoriasis, certain forms of erythema and urticaria, and some cases of asthma are due to this cause. Milk, eggs, meat, shell fish, strawberries, etc., are among the foods concerned. Duke has drawn attention to the importance of recognizing that severe *abdominal pain* may be due to food allergy. The use of skin tests made with the isolated protein is an important diagnostic measure.

In the *treatment* it may be possible to avoid the particular food to which the patient is sensitized. Otherwise an immunity may be obtained by giving very minute doses of the protein concerned, insufficient to produce a reaction, and gradually increasing the amount. Children often lose the hypersusceptibility as they grow older.

IX. METHYL CHLORIDE POISONING

Methyl chloride is used in refrigeration and poisoning occurs from leaking pipes. The main symptoms are headache, vertigo, drowsiness, mental confusion, convulsions, coma, stupor, weakness, cyanosis, nausea, vomiting and abdominal pain. Fever occurs about 36 hours after the poisoning with rapid pulse and respiration, and low blood pressure. The pupils are dilated and occasionally strabismus, ptosis and nystagmus are found. The blood shows anæmia with leucocytosis. There is an acetone odor to the breath and acetone is found in the urine, unless there is anuria, which is common. The coma may persist for two to three days. Death is due to respiratory paralysis and may be preceded by convulsions. Sequelæ may be in the form of mental changes or ataxia. The diagnosis has to be made from food poisoning, methyl alcohol and carbon monoxide poisoning, mercury and strychnia poisoning, encephalitis and meningitis. In *treatment* the acidosis should be met by sodium bicarbonate freely by mouth or bowel with dextrose, alkaline solution intravenously, and oxygen. Caffeine and digitalis may be needed for the circulation.

SECTION IV

DEFICIENCY DISEASES

I. PELLAGRA

Definition.—A deficiency disease, with periodical manifestations characterized by gastro-intestinal disturbances, skin lesions, and a tendency to changes in the nervous system.

Historical.—The disease appears to have been endemic in Spain by 1735 and the first description is by Cazal (1762), who named it *mal de la rosa*. It existed in Italy in 1750 and was described in 1771 by Frapolli, who gave it the name of pellagra (rough skin). By the eighteenth century it had spread over northern Italy and had appeared in France and Roumania. It is quite probable that there have been sporadic cases in the United States for the last fifty years.

Distribution.—The disease is prevalent in parts of southern Europe, particularly in Italy and Roumania. It exists in Spain, Portugal, France, Egypt and the United States, in the southern part of which country it spread with extraordinary rapidity some years ago. In 1917 there were 3,666 deaths and 3,344 deaths in 1925 in the U. S. registration area. Better diagnosis can hardly explain the frequency, as the disease is so striking in its manifestations that many cases could hardly be overlooked. The disease is sometimes one of particular localities, as beri-beri; it is a disease of the country more than of the cities in Europe, but in the United States many towns and villages show a number of cases. As regards the influence of place, the number of cases in the asylums of the United States is significant. A few cases have occurred in England.

Etiology.—This has been the subject of much controversy and investigation, and finality has not been reached. Diet plays the most important rôle in the causation, perhaps partly in the food balance and also in the lack of a pellagra preventive (P. P.) factor for which the name vitamin G has been suggested. As regards the protein supply, "the dominating rôle of diet in the development of the disease would seem referable to a specific quality of the amino-acid make-up of the protein supply (Goldberger)." The exact combination (or combinations) is not clear. Yeast contains the largest amount of the preventive factor so far as known at present. It is possibly present in foods which contain the anti-neuritic vitamin. The view that it is due to an infection has little support.

AGE.—The disease occurs at any age, but the majority of cases are between twenty and forty years. As regards races, the negro is more susceptible

than the white, and women are, as a rule, slightly more susceptible than men.

OCCUPATION.—In Europe the disease is almost confined to laborers of the poorer classes, but this is not true of the United States.

SEASON.—The disease occurs particularly in the spring and sometimes in the autumn, both in its onset and recurrences.

Pathology.—There is nothing characteristic in the morbid anatomy. In the acute cases there may be atrophy of the walls of the intestines, fatty degeneration of the internal organs and changes in the nervous system. The alterations in the cord are fairly constant. There is degeneration of the lateral columns in the dorsal region and of the posterior columns in the cervical and dorsal regions. In the brains of patients with mental deterioration atrophy of the cerebrum is found.

Symptoms.—These vary markedly in severity, usually appearing in the spring and sometimes in the autumn. There is always a tendency to recurrence, and with each succeeding attack more damage is done, particularly to the nervous system. The onset is usually in the spring with indefinite symptoms, such as weakness, headache, and depression.

DIGESTIVE TRACT.—Disturbance of the alimentary tract is usually an early symptom. In the mouth there may be sensations of heat, with loss of taste. Stomatitis and salivation are common, the mucous membrane is very red, ulcers may appear and the epithelium is stripped off, leaving a raw surface so that chewing is painful. Anorexia, nausea and vomiting are frequent; there is also diarrhoea, sometimes dysentery, often severe and accompanied by pain, the stools being serous or bloody. It may alternate with constipation. Hydrochloric acid in the stomach is often absent or greatly reduced.

SKIN.—The erythema usually begins on the backs of the hands and at first resembles an ordinary sunburn. There may be puffy swelling. The affected areas are symmetrical and sharply defined as a rule, extending above the wrist and down to the last finger joint. The face, neck and feet may be affected in the same way. The process may not advance any further, the skin becomes darker and desquamates, some pigmentation remaining. In other cases vesicles and bullæ form, containing serum or pus. These dry gradually, with the production of fissures. After drying and desquamation the skin may have a dry appearance and a deep red color. With repeated attacks the skin may become indurated, thickened and dark; later atrophy and thinning follow. Exposure to the sun may have an influence on the eruption but is not the cause. The erythema occurs sometimes on protected parts.

NERVOUS SYSTEM.—Headache and vertigo are common. Mental features are often marked, among which are confusion, dullness, lassitude, irritability, feelings of anxiety and depression, change in the disposition, and hallucinations of sight and hearing. These may progress to profound depression and ultimately to dementia. Mania occurs sometimes and suicidal tendencies are not uncommon. The symptoms due to changes in the cord vary with the lesion. A spastic condition, disturbances of sensation, paralysis of the sphincters, or loss of the reflexes of the legs may be found.

The blood shows no special features beyond those of a secondary anæmia. The temperature is usually normal except in some of the acute cases.

Clinical Forms.—The disease occurs in two main forms, an acute and a chronic recurrent form. In the acute form there are fever, marked prostra-

tion, severe diarrhœa, delirium or stupor and a rapid downward course. Death may occur in a few weeks from the onset. These cases seem to be more frequent in the United States than in Europe. In the *chronic* form the manifestations are not severe, but tend to recur each year, and each attack leaves the patient in a worse condition. There is always the tendency to mental deterioration which occurs in fully 10 per cent. of the cases. Death occurs from exhaustion and cachexia, or some intercurrent disease. Fortunately, succeeding attacks are not necessarily more severe than the preceding ones. There are instances of this form persisting for twenty-five years.

Cases without the skin lesions—pellagra sine pellagra—have been described.

Diagnosis.—A typical case offers no difficulties, but in the absence of the skin lesions considerable difficulty may be experienced. Scurvy might give difficulty, but the absence of the other features of pellagra should be conclusive.

Skin lesions of the nature of erythema might cause confusion, but the absence of the general features removes doubt. The study of the stools differentiates it from sprue. The psychical features might suggest general paresis, but the skin lesions and digestive disturbance should make the diagnosis clear. The acute cases might be mistaken for various infections, but the erythema and gastro-intestinal features should prevent this.

Prognosis.—In the United States the outlook is regarded as serious, if not as regards death, certainly as regards ultimate recovery. In Europe, where the disease has existed for a long time, the prognosis is more favorable, and in Italy in some years the mortality was only 4 per cent. In cases with acute features or fever the prognosis is grave and signs of severe toxæmia or of mental involvement are ominous. Erythema of a moist character is regarded as a grave sign. Any complications should be regarded seriously. The prognosis is best in the chronic cases without mental features. The outlook is serious in asylum cases.

Prophylaxis.—Improvement in the living conditions and good sanitation are important in prevention. Too much corn or maize should not be used, particularly in institutions. A diet rich in animal protein food is the essential with a sufficient amount of milk, eggs, meat and vegetables, especially beans.

Treatment.—The patient should be placed in the best general conditions and a change of diet and climate is advisable. Rest in bed is necessary while the symptoms are acute. The diet should be as nutritious as possible and the diarrhœa need not interfere with sufficient nourishment. Fresh milk, buttermilk, eggs, fresh meat and fresh or dried vegetables should be taken in full amounts. Yeast in some form should be given freely and also salt. Dilute hydrochloric acid (3 i, 4 c. c. twice after each meal) should be taken. Atoxyl and arsphenamine have been used but arsenic by mouth, as Fowler's solution, is apparently more useful. Transfusion of blood, both from healthy individuals and those who have recovered from the disease, has apparently given good results. Symptomatic treatment and a proper diet seem to have been as successful as any special measure.

Any other disease, such as hookworm infection, should receive treatment.

II. BERI-BERI

(Kakke, Endemic Multiple Neuritis)

Definition.—A disease due to deficiency of the anti-neuritic vitamin, and characterized by multiple neuritis, anasarca, and muscular atrophy.

It seems probable that several forms of multiple neuritis have been described under the term beri-beri. The form which is particularly common in China and Japan is due to a diet deficient in the anti-neuritic vitamin (water soluble B) which occurs in the outer layer of rice.

History.—The disease is believed to be of great antiquity in China, and is possibly mentioned in the oldest known medical treatise. In the early years of the nineteenth century it attracted much attention among the Anglo-Indian surgeons, and we may date the modern scientific study of the disease from Malcolmson's monograph, published at Madras in 1835. The opening of Japan gave an opportunity to the European physicians holding university positions, particularly Anderson, Baelz, Scheube, and Grimm, to investigate the disease. The studies of Japanese physicians, particularly Miura and Takagi, and of Dutch physicians in the East, have contributed much to our knowledge. The studies of Schaumann, Fraser, Stanton, and others and the dietetic experiments in the Philippines have confirmed the older views that it is a disorder depending upon an imperfect dietary.

Distribution.—It is specially prevalent among the Malays, Chinese and Japanese, and during the Russian War more than 50,000 cases occurred in the Japanese army. It prevails in the Philippines. In India it is less common. Localized outbreaks have occurred in Australia. It prevails in parts of South America, and in the West Indies. It is met with among the fishermen of Norway and of the Newfoundland Banks. It occurs also in asylums, in which there have been severe outbreaks in the United States.

Etiology.—The deficiency is in the lack of the anti-neuritic vitamin which is present in the germ and pericarp of cereals, in peas, beans, carrots and potatoes, in milk, eggs, certain meats and in yeast. There is no special association with rice; in the areas where the disease is most prevalent, a large source of the vitamin is from rice in which it is situated in the pericarp. The occurrence of the disease on ships and in institutions is due to the same deficiency in the diet. Crowding, poor hygienic conditions and hot moist seasons seem to favor the occurrence of the disease. Some believe that infection is necessary in addition to the vitamin deficiency.

Morbid Anatomy.—The most constant and striking features are changes in the peripheral nerves and degenerative inflammation involving the axis cylinder and medullary sheaths. In acute cases this is found not only in the peripheral nerves, but also in the vagus and phrenic. The fibres of the voluntary muscles, as well as of the myocardium, are much degenerated. The changes are regarded as due largely to water retention and swelling, especially in the nerves and striated muscles.

Symptoms.—The disease occurs in various forms:

(a) The INCOMPLETE OR RUDIMENTARY FORM sets in with catarrhal symptoms, followed by pains and weakness in the limbs and a lowering of the sensibility in the legs, with the occurrence of paræsthesia. Slight œdema some-

times appears. After a time paræsthesia is felt in other parts of the body, and the patient may complain of palpitation of the heart, uneasy sensations in the abdomen, and sometimes shortness of breath. There may be weakness and tenderness of the muscles. After a few days to months, these symptoms disappear, but with the return of warm weather there may be a recurrence.

(b) The ATROPHIC FORM sets in with much the same symptoms, but the loss of power in the limbs progresses more rapidly, and soon the patient is no longer able to walk or to move the arms. The atrophy, which is associated with a good deal of pain, may extend to the muscles of the face. The œdematous symptoms and heart disturbance play a minor rôle in this form, which is known as the dry or paralytic variety.

(c) WET OR DROPSICAL FORM.—Setting in as in the rudimentary variety, the œdema soon becomes the most marked feature, extending over the whole subcutaneous tissue, and with effusions into the serous sacs. The atrophy of the muscles and disturbance of sensation are not so prominent but palpitation and rapid action of the heart and dyspnœa are common. The wasting may not be apparent until the dropsy disappears.

(d) The ACUTE, PERNICIOUS, OR CARDIAC FORM is characterized by acute cardiac failure, especially of the right heart, coming on rapidly after the existence of slight symptoms. Death may follow within twenty-four hours; more commonly the symptoms extend over several weeks. Widespread paralysis with anæsthesia may be present.

The mortality varies greatly, from 2 or 3 per cent. to 40 or 50 per cent. among the coolies in certain settlements of the Malay Archipelago.

Diagnosis.—In tropical countries there is rarely any difficulty. In cases of peripheral neuritis, associated with œdema, coming from tropical ports, the possibility of this disease should be remembered. The peculiar epidemic dropsy of Calcutta and Bengal is probably beri-beri. Greig has shown it to be a nutritional disorder associated with the use of polished rice.

Prophylaxis.—Much has been done to prevent the disease by diets containing sufficient amounts of vitamins such as beans, peas, barley, potatoes, eggs and fresh meat. Polished rice should not be used for food.

Treatment.—It is a very chronic and obstinate malady. A nutritious diet rich in the lacking vitamins, rest in bed, purgation for the dropsy, cardiac stimulants, and the usual measures for the neuritis are the important factors. Dry powdered yeast (one ounce a day) or the concentrated form and malt extract are especially useful. Salicylates and saline laxatives are used in Japan. If the cardiac features are marked the usual treatment with active stimulation should be employed. When the œdema has subsided massage, passive movements, and electricity may be used for the atrophic muscles.

III. SCURVY

(*Scorbutus*)

Definition.—A disorder of metabolism due to deficiency of anti-scorbutic vitamin, characterized by great debility, with anæmia, a spongy condition of the gums, and a tendency to hæmorrhages.

Etiology.—The disease has been known from the earliest times, and has prevailed particularly in armies in the field and among sailors on long voyages. It has been well called “the calamity of sailors.” Owing largely to the efforts of Lind and to a knowledge of the etiological conditions, scurvy has disappeared from the naval service. In the mercantile marine cases still occasionally occur, owing to the lack of proper food.

In parts of Russia scurvy is endemic. In the United States scurvy is not a very rare disease. To the hospitals in the seaport towns sailors are now and then admitted with it. In large almshouses outbreaks occasionally occur. A great increase of foreign population of a low grade has made the disease not uncommon in certain districts. In the mining districts of Pennsylvania the Hungarian, Bohemian, and Italian settlers are not infrequently attacked. Their diet is often composed largely of bread, coffee, and meat. Occasionally one meets with scurvy among quite well-to-do people. In Great Britain and Ireland it has become rare. It is not uncommon in the South African natives.

The essential cause is a lack of the anti-scorbutic vitamin (probably water-soluble C). This is present in green vegetables, fresh fruit juices, especially of oranges and lemons, in roots and tubers and in small amounts in milk. It is very sensitive to oxidation, heat and drying and is destroyed by alkalis (hence the effect of sodium bicarbonate when used in cooking vegetables).

Other factors may play a slight part, particularly bad hygienic conditions—overcrowding, cold, damp quarters, and prolonged fatigue under depressing influences. Exposure to scorbutic conditions for four to six months is usually necessary. The disease attacks all ages. Sex has no special influence, but during the siege of Paris it was noted that the males attacked were greatly in excess of the females.

Morbid Anatomy.—The anatomical changes are marked but not specific, and are chiefly those associated with hæmorrhage. The skin shows the ecchymoses evident during life. There are hæmorrhages into the muscles, under the periosteum, and occasionally about or even into the joints. Hæmorrhages occur particularly on the serous membranes and in the kidneys and bladder. The gums are swollen and sometimes ulcerated. Ulcers are occasionally met with in the ileum and colon. Hæmorrhages into the mucous membranes are extremely common. The spleen is enlarged and soft. Parenchymatous changes are constant in the liver, kidneys, and heart.

Symptoms.—The disease is insidious in its onset. Early symptoms are loss in weight, progressive weakness, and pallor. Swelling of the pinna of the ear, which may extend to the scalp, has been noted early. Very soon the gums become swollen and spongy, bleed easily, and in extreme cases present a fungous appearance. These changes, regarded as characteristic, are sometimes absent. The teeth may become loose and even fall out. Actual necrosis of the jaw is not common. The breath is excessively foul. The tongue is swollen, but may be red and not much furred. The salivary glands are occasionally enlarged. Hæmorrhages beneath the mucous membranes of the mouth, especially on the hard palate, are common. The skin becomes dry and rough, and ecchymoses soon appear, first on the legs and then on the arms and trunk, and particularly into and about the hair-follicles. They are petechial, but may become larger, and when subcutaneous may cause distinct swellings. In severe cases, particularly in the legs, there may be effusion

between the periosteum and the bone, forming irregular nodes, which may break down and form foul-looking sores. The slightest bruise or injury causes hæmorrhages into the injured part. (Edema about the ankles is common. The "*scurvy sclerosis*," seen oftenest in the legs, is a remarkable infiltration of the subcutaneous tissues and muscles, forming a brawny induration, the skin over which may be blood-stained. Hæmorrhages from the mucous membranes are less constant; epistaxis is, however, frequent. Conjunctival hæmorrhage is not uncommon. Hæmoptysis and hæmatemesis are uncommon. Hæmaturia, often microscopic, is common and bleeding from the bowels may occur in severe cases.

Palpitation of the heart with a feeble and irregular impulse is common. The heart may be enlarged, especially the right ventricle, and the rate increased. A hæmic murmur can usually be heard at the base. Secondary anæmia is usual; the leucocytes vary and there may be a leucopenia or an increase with lymphocytosis. Hæmorrhagic infarction of the lungs and spleen has been described. Respiratory symptoms are not common. The appetite is impaired, and owing to the soreness of the gums the patient is unable to chew. Constipation is more frequent than diarrhœa. The urine is often albuminous, the amount usually reduced and the specific gravity high.

There are mental depression, indifference, in some cases headache, and in the later stages delirium. Cases of convulsions, or hemiplegia, and of meningeal hæmorrhage have been described. Remarkable ocular symptoms are occasionally met with, such as night-blindness or day-blindness, associated with anæmia of the retina. Changes in the optic disk have been found.

In advanced cases necrosis of the bones may occur, and in young persons even separation of the epiphyses. There are instances in which the cartilages have separated from the sternum. The callus of a recent fracture may undergo destruction. Fever is not present, except in the later stages, or when secondary inflammations in the internal organs appear. The temperature may be below normal. Acute arthritis is an occasional complication.

Diagnosis.—No difficulty is met in the recognition of scurvy when a number of persons are affected together. In isolated cases the disease is distinguished with difficulty from certain forms of purpura. Mercurial stomatitis does not show the other features of scurvy and acute leukæmia is recognized by the blood picture. The association with manifest insufficiency in diet, and the rapid amelioration with suitable food, are helpful points.

Prognosis.—The outlook is good, unless the disease is far advanced and the conditions persist which lead to its occurrence. Death results from gradual heart-failure, occasionally from sudden syncope. Meningeal hæmorrhage, gangrene of the lung, extravasation into the serous cavities, enterocolitis, and intercurrent affections may prove fatal.

Prophylaxis.—This depends on a proper supply of antiscorbutic vitamin. The fresh juice of oranges and lemons, fresh uncooked vegetables, tomatoes (fresh or canned), cabbage, potatoes, meat and milk are the most useful.

Treatment.—The juice of two or three lemons or oranges daily and a full diet of meat and fresh vegetables suffice to cure all cases of scurvy, unless far advanced. When the stomach is much disordered, small quantities of scraped meat and milk should be given at short intervals, and orange juice in gradually increasing quantities. Mashed potato, mixed with milk, is useful.

As the patient gains in strength the diet may be more liberal, and he may eat freely of potatoes, cabbage, water-cress, and lettuce. The stomatitis causes great distress and a permanganate of potash (1-2 per cent.) or dilute phenol (0.5 per cent.) solution forms a good mouth-wash. A solution of nitrate of silver applied to the gums is useful. The constipation is best treated with large enemata. For other conditions, such as hæmorrhage and ulceration, suitable measures must be employed.

INFANTILE SCURVY (*Barlow's Disease*)

A special form of scurvy occurs in children which differs from the adult form only in the changes occurring in structures which are different in early life. W. B. Cheadle and Gee, in London, described in very young children a cachexia associated with hæmorrhage. Cheadle regarded the cases as scurvy ingrafted on a rickety stock. Gee called his cases periosteal cachexia. The condition had previously been regarded as acute rickets. A few years later Barlow made an exhaustive study of the affection with careful anatomical observations and it is now recognized as infantile scurvy, and called Barlow's disease.

Etiology.—The disease usually appears between the sixth and twelfth month and is rare after the second year. The essential cause is the absence of the anti-scorbutic vitamin. A diet of condensed or malted milk seems to be most often responsible, sometimes sterilized or boiled milk, pasteurized milk rarely. In the rare cases in which the child has been breast fed, the mother's diet was insufficient in the anti-scorbutic vitamins.

Symptoms.—The following summary is taken from Barlow:

"So long as it is left alone the child is tolerably quiet; the lower limbs are kept drawn up and still; but when placed in its bath or otherwise moved there is continuous crying, and it soon becomes clear that the pain is connected with the lower limbs. At this period the upper limbs may be touched with impunity, but any attempt to move the legs or thighs gives rise to screams. Next, some obscure swelling may be detected, first on one lower limb, then on the other, though it is not absolutely symmetrical. . . . The swelling is ill-defined, but is suggestive of thickening round the shafts of the bones, beginning above the epiphyseal junctions. Gradually the bulk of the limbs affected becomes visibly increased. . . . The position of the limbs becomes somewhat different from what it was at the outset. Instead of being flexed they lie everted and immobile, in a state of pseudo-paralysis. . . . About this time, if not before, great weakness of the back becomes manifest. A little swelling of one or both scapulæ may appear, and the upper limbs may show changes. These are rarely so considerable as the alterations in the lower limbs. There may be swelling above the wrists, extending for a short distance up the forearm, and some swelling in the neighborhood of the epiphyses of the humerus. There is symmetry of lesions, but it is not absolute; and the limb affection is generally consecutive, though the involvement of one limb follows very close upon another. The joints are free. In severe cases another symptom may now be found—namely, crepitus in the regions adjacent to the junctions of the shafts with epiphyses. The upper and lower extremities of the femur, and the upper extremity of the tibia, are the common

sites of such fractures; but the upper end of the humerus may also be so affected. . . . A very startling appearance may be observed at this period in the front of the chest. The sternum, with the adjacent costal cartilages and a small portion of the contiguous ribs, seems to have sunk bodily back, *en bloc*, as though it had been subjected to some violence which had fractured several ribs in the front and driven them back. Occasionally thickenings of varying extent may be found on the exterior of the vault of the skull, or even on some of the bones of the face. . . . Here also must be mentioned a remarkable eye phenomenon. There develops a rather sudden proptosis of one eyeball, with puffiness and very slight staining of the upper lid. Within a day or two the other eye presents similar appearances, though they may be of less severity. The ocular conjunctiva may show a little ecchymosis, or may be quite free. With respect to the constitutional symptoms accompanying the above series of events the most important feature is the profound anæmia which is developed. . . . The anæmia is proportional to the amount of limb involvement. As the case proceeds there is a certain earthy-colored or sallow tint, which is noteworthy in severe cases, and when once this is established bruise-like ecchymoses may appear, and more rarely small purpura. Emaciation is not a marked feature, but asthenia is extreme and suggestive of muscular failure. The temperature is very erratic; it is often raised for a day or two, when successive limbs are involved, especially during the tense stage, but is rarely above 101° or 102° F. At other times it may be normal or subnormal."

If the teeth have appeared the gums may be spongy.

The essential lesion is a subperiosteal blood extravasation, which causes the thickening and tenderness in the shafts of the bones. In some instances there is hæmorrhage in the intramuscular tissue. Petechiæ and subcutaneous hæmorrhages are rare; hæmaturia is the only common hæmorrhage.

Diagnosis.—In young children with difficulty in moving the legs, or in whom paralysis is suspected, the condition should always be looked for. What is known sometimes as Parrot's disease, or syphilitic pseudo-paralysis, may be confounded with it. In it the loss of motion is more or less sudden in the upper or lower limbs, or in both, due to a solution of continuity and separation of the cartilage at the end of the diaphysis. There are usually crepitation and much pain on movement. The diagnosis from osteomyelitis or epiphysitis may be difficult but high fever is against scurvy. Rheumatic fever is rare below the age of two years. In mild forms of scurvy the tenderness on handling or a puzzling hæmaturia may be the most marked features.

A study of the diet and the results of treatment are important aids.

The prophylaxis is most important. The proprietary forms of condensed milk and preserved foods for infants should not be used. The fresh or pasteurized cow's milk should be given and a teaspoonful of meat-juice or gravy may be added with a little mashed potato. After the first month every infant on artificial feeding should be given one teaspoonful of orange juice (with a little sugar if sour), increased to half an ounce at three months of age.

Treatment.—The child should be handled carefully, carried on a pillow and the affected part supported by light splints or wrapped in cotton wool with a light bandage. Orange juice or lemon juice should be given freely and foods containing the anti-scorbutic vitamins. Recovery is usually prompt and satisfactory.

IV. RICKETS (RACHITIS)

Definition.—A disease of infants, characterized by impaired nutrition of the entire body and alterations in the growing bones.

Glisson, the anatomist of the liver, accurately described the disease in 1650. The name is derived from the old English word *wrickken*, to twist. Glisson suggested to change the name to rachitis, from the Greek $\rho\acute{\alpha}\chi\iota\varsigma$, the spine, as it was one of the first parts affected, and also from the similarity in the sound to rickets.

Etiology.—Rickets exists in all parts of the world, but is particularly marked among the poor of the larger cities, who are badly housed and ill fed. It is much more common in Europe than in America. In Vienna and London from 50 to 80 per cent. of children at the clinics present signs of rickets. In the cities of the United States it is very prevalent, particularly among the children of the negro and Italian races. There is a seasonal incidence associated with the amount of sunlight; rickets increases in the autumn and through the winter reaching its maximum in March. Rickets affects male and female children equally. It is particularly a disease of the first and second years of life, rarely beginning before the sixth month. Jenner described a late rickets, in which the disease may not appear until the ninth or even the twelfth year, or later (the osteomalacia of puberty). There is no evidence that the disease is hereditary or due to syphilis. Poor hygienic conditions, apart from lack of sunlight, probably play a part. The disease is often seen in children in whose diet there is a large amount of carbohydrates but little of animal fats.

There is a failure of calcification of the bones which is associated with a change in the normal proportions of calcium and phosphorus in the blood. Normally there is 10 mg. of calcium in 100 c. c. of blood and the calcium content is normal in rickets but the phosphorus content of 5 mg. usually falls below 3 mg. per 100 c. c. of blood. The diminished phosphorus content is associated with a decrease of the antirachitic vitamin in the diet or insufficient formation of this vitamin in the body. This vitamin is present in animal fats in variable amounts and in human milk but cod-liver oil is the most abundant source. It is also formed in the skin by the influence of the ultra-violet radiations, whether from sunlight or from artificial ultra-violet rays, on cholesterol in the skin. Ergosterol, after treatment with ultra-violet rays, is powerfully antirachitic.

Morbid Anatomy.—Glisson's original description of the external appearances of a rickety child is remarkably complete; indeed, his monograph is an enduring monument to the skill and powers of observation of this great physician. "(1) An irregular or unusual proportion of its parts. The head is evidently larger than normal, and the face fatter in respect to the other parts. . . . (2) The external members and muscles of the whole body are seen to be delicate and emaciated, as though consumed by atrophy or tabes, and this (so far as we know) is always observed in those dead of this affection. (3) The whole skin, both the true and the fleshy and fatty layers, is flaccid and rather pendulous, like a loose glove, so that you think it could hold much more flesh. (4) About the joints, especially in the wrists and ankles, there

are certain protuberances which, if opened, are seen to arise, not in the fleshy or membranous parts, but in the ends of the bones themselves, especially in their epiphyses. (5) The joints, limbs, and habitus of all these external parts are less firm and rigid, less inflexible than in other dead bodies, and the neck scarcely becomes rigid, a frigore, post mortem, or to a less extent than in other cadavers. (6) The chest externally is thin and much narrowed, especially beneath the scapulæ, as though compressed from the sides, and the sternum acuminate like the keel of a ship or the breast of a fowl. (7) The ends of the ribs which join with the cartilages of the sternum are nodular, like the ends of the wrists and ankles." He also described the prominent abdomen, the enlarged liver, and the changes in the mesenteric glands.

The bones show the most important changes, particularly the ends of the long bones and the ribs. Between the shaft and epiphyses a slight bulging is apparent, and, on section the zone of proliferation, which normally is represented by two narrow bands, is greatly thickened, bluish in color, more irregular in outline, and very much softer. The width of this cushion of cartilage varies from 5 to 15 mm. The line of ossification is also irregular and more spongy and vascular than normal. The periosteum strips off very readily from the shaft, and beneath it there may be a spongy tissue not unlike decalcified bone. The outcome is an imperfect ossification, so that the bone has neither the natural rate of growth nor the normal firmness. In the cranium there may be large areas, particularly in the parieto-occipital region, in which ossification is delayed, so that the bone yields readily to pressure with the finger. There are localized depressed spots of atrophy, which, on pressure, give the so-called "parchment crackling." Flat hyperostoses arise on the outer table, particularly on the frontal and parietal bones, producing the characteristic broad forehead with prominent frontal eminences, a condition sometimes mistaken for hydrocephalus. The chemical analysis of rickety bones shows a marked diminution in calcium, which may be as low as 25 or 35 per cent. instead of the normal 60 per cent.

The liver and spleen are usually enlarged, and sometimes the mesenteric glands. As Gee suggested, these conditions probably result from the general state of the health associated with rickets. Beneke has described a relative increase in the size of the arteries in rickets.

Symptoms.—The disease comes on insidiously about the period of dentition, before the child begins to walk. Mild grades of it are often overlooked. In many cases digestive disturbances precede the appearance of the characteristic lesions, and the nutrition of the child is markedly impaired. There is usually slight fever, the child is irritable and restless, and sleeps badly. If he has already walked, he now shows a marked disinclination to do so, and seems feeble and unsteady in his gait. Sir William Jenner called attention to three general symptoms of great importance: First, a diffuse soreness of the body, so that the child cries when an attempt is made to move it, and prefers to keep perfectly still. Secondly, slight fever (100° to 101.5° F.), with nocturnal restlessness, and a tendency to throw off the bedclothes. This may be partly due to the fact that the general sensitiveness is such that even their weight may be distressing. Thirdly, profuse sweating, particularly about the head and neck, so that the pillow is soaked with perspiration.

The tissues become soft and flabby; the skin is pale; and from a healthy,

plump condition the child becomes puny and feeble. The muscular weakness may be marked, particularly in the legs, and paralysis may be suspected. This so-called pseudo-paralysis of rickets results in part from the flabby, weak condition of the legs and in part from the pain associated with the movements. Coincident with, or following closely upon, the general symptoms the characteristic *skeletal lesions* are observed. Among the first of these are the changes in the ribs, at the junction of the bone with the cartilage, forming the so-called rickety rosary. When the child is thin these nodules may be distinctly seen, and in any case can be easily made out by touch. They very rarely appear before the third month. They may increase in size up to the second year, and are rarely seen after the fifth year. The thorax undergoes important changes. Just outside the junction of the cartilages with the ribs there is an oblique, shallow depression extending downward and outward. A transverse curve, sometimes called Harrison's groove, passes outward from the level of the ensiform cartilage toward the axilla, and may be deepened at each inspiration. It is rendered more prominent by the eversion and prominence of the costal border. The sternum may project, particularly in its lower half, forming the so-called pigeon or chicken breast. These changes in the thorax are not peculiar to rickets, and are more commonly associated with hypertrophy of the tonsils, or anything which interferes with the free entrance of air into the lungs. The spine is often curved posteriorly, the processes are prominent; lateral curvature is not so common.

The head of a rickety child usually looks large in proportion to the body and the face, and the fontanelles remain open for a long time. There are areas, particularly in the parieto-occipital regions, in which ossification is imperfect; and the bone may yield to the pressure of the finger, to which the term cranio-tabes has been given. Coincidentally with this, hyperplasia proceeds in the frontal and parietal eminences, so that these increase in thickness, and may form irregular bosses. In one type the skull may be large and elongated, with the top considerably flattened. In another, and perhaps more common, case the shape of the skull, when seen from above, is rectangular—the *caput quadratum*. The forehead is broad and square, and the frontal eminences marked. The anterior fontanelle is late in closing, and may remain open until the third or fourth year. The skin is thin, the veins are full and prominent, and the hair is often rubbed from the back of the skull.

A systolic murmur may frequently be heard over the anterior fontanelle or in the temporal region. This, first described by John D. Fisher, of Boston, in 1833, is heard with the greatest frequency in rickets, but its presence in healthy infants has been amply demonstrated. The murmur is rarely present after the fifth year. A knowledge of the existence of this murmur may prevent errors. A case was reported as an instance of tumor of the brain.

Changes occur in the bones of the face, chiefly in the maxillæ, which are reduced in size. The normal process of dentition is much disturbed and late teething is a marked feature. The teeth may be small and badly formed.

Changes in the scapulæ are not common. The clavicle may be thickened at the sternal end and near the attachment of the sterno-cleido-mastoid muscle. The most noticeable changes are at the lower ends of the radius and ulna. The enlargement is at the junction-area of the shaft and epiphysis. Less evident enlargements may occur at the lower end of the humerus. In

severe cases the natural shape of the bones of the arm may be much altered, since they have had to support the weight of the child in crawling on the floor. The changes in the pelvis are of special importance, particularly in female children, as in extreme cases they lead to great deformity. In the legs, the lower end of the tibia first becomes enlarged; and in slight cases it may alone be affected. In the severe forms the upper end of the bone, the corresponding parts of the fibula, and the lower end of the femur become greatly thickened. If the child walks, slight bowing of the tibiæ inevitably results. In more advanced cases the tibiæ, and even the femora, may be arched forward. In other instances knock-knee occurs. Unquestionably the chief cause of these deformities is the weight of the body, but muscular action takes part in it. The green-stick fracture is not uncommon in the soft bones of rickets.

These changes in the skeleton proceed slowly, and the general symptoms vary a good deal with their progress. The child becomes more or less emaciated, though "fat rickets" is by no means uncommon, and a child may be well nourished but "pasty" and flabby. Fever is not constant, but in actively progressing changes in the bone there is usually a slight pyrexia. The abdomen is large, "pot-bellied," due partly to flatulent distention, partly to enlargement of the liver, and in severe cases to diminution of the volume of the thorax. The spleen is often enlarged and readily palpable. The urine is stated to contain an excess of lime salts. There is usually some secondary anemia; a leucocytosis may or may not be present; it is more common with enlargement of the spleen (Morse). Many rickety children show marked nervous symptoms; irritability, peevishness, and sleeplessness are constantly present. Jenner called attention to the close relationship between rickets and infantile convulsions, particularly to the fits which occur after the sixth month. Tetany is by no means uncommon. Laryngismus stridulus is a common complication, and more frequent in rickety children. Rachitic children are very susceptible to respiratory-tract infections. Severe rickets interferes seriously with the growth of a child. Extreme examples of rickety dwarfs are not uncommon.

Late Rickets.—The disease may set in from the tenth to the fourteenth year, either for the first time or in a child rickety in infancy. The long bones are involved, with enlargement of the epiphyses and a marked tendency to deformity.

Diagnosis.—The condition exists before we can diagnose it clinically. In ordinary cases, the open fontanelle, delayed dentition and the changes in the bones are characteristic, but it is often overlooked because not looked for. The radiographic picture is characteristic, especially of the lower ends of the radius, ulna and femur. The bones show a diminished shadow due to imperfect ossification. The ends of the bones are broadened, the surface irregular with a shadowy fringe, and concave and irregular. Development of the carpal bones may be delayed.

Prognosis.—The disease is rarely in itself fatal, but the condition of the child is such that it is readily carried off by intercurrent affections, particularly those of the respiratory organs. The loss of rigidity in the thorax results in a reduction in its size and loss of the power of expansion. Spasm of the larynx and convulsions occasionally cause death. In females the deformity of the pelvis is serious, as it may lead to difficulties in parturition.

Prevention.—The better the condition of the mother during pregnancy the less likelihood there is of rickets in the child. Of the general treatment, attention to the feeding of the child is important. If the mother is unhealthy, or cannot nurse the child, a suitable wet-nurse should be provided, or the

child must be artificially fed, in which case cow's milk, diluted according to the age of the child, should constitute the chief food. Barley-water and carefully strained and well-boiled oatmeal gruel form excellent additions. Later sufficient fat should be given and too much starchy food avoided. Egg yolk is useful; half the yolk of a raw egg can be given to infants of one or two months and the whole yolk after this age. Small amounts of cod-liver oil (10 drops three times a day) and exposure to sunlight for two hours a day are preventive. Ultra-violet radiation given for 15 minutes a month prevents rickets in infants up to eight months of age. The intervals between exposures should not be over two weeks. At first exposures of one minute anteriorly and posteriorly may be given and increased by one minute each exposure up to five minutes front and back with a total of ten minutes per week.

Treatment.—The child should be warmly clad and in the open air and sunshine as much as possible. The child should be bathed daily in warm water. Careful friction with sweet oil is advantageous, and, if properly performed, allays rather than aggravates the sensitiveness. Special care should be taken to prevent deformity. The child should not be allowed to walk, and for this purpose splints applied so as to extend beyond the feet are very effective. There are three specifics—cod-liver oil, sunlight or ultra-violet light rays and irradiated ergosterol (viosterol). The cod-liver oil does not require to be given in large doses—10 drops three times a day is enough. The exposure to sunlight for two hours a day is sufficient. The ultra-violet rays should be given for gradually increasing periods (one to twenty minutes). Care should be taken not to blister the skin. The dose of viosterol depends on its relative strength as compared with standardized cod-liver oil. There seems to be a possibility of harm from overdosage in young children. The syrup of the iodide of iron may be given with the oil. The digestive disturbances, together with the complications, should receive appropriate treatment. Orthopedic treatment may be required for the deformities.

SECTION V

DISEASES OF METABOLISM

I. GOUT

(*Podagra*)

Definition.—A disorder of metabolism associated with retention of uric acid and of other purin bodies in the body, characterized clinically by attacks of acute arthritis, the deposition of sodium urate in and about the joints, and by the occurrence of irregular constitutional symptoms.

Etiology.—The purin bodies, adenin, guanin, hypoxanthin, xanthin, and uric acid, result from the transformation of the nucleo-proteins of the food and of the tissues by ferments or enzymes, each one of which has its own specific action. Among the proteolytic enzymes nuclease has a universal distribution, and, no matter what the source of the nucleo-protein, it sets free adenin and guanin. Specific enzymes also liberate uric acid from the nucleo-proteins of the tissues and from the purins of the food. Once formed, the difficulty is to get rid of uric acid, and this appears to be one essential factor in the etiology of gout. Birds and serpents, unable to oxidize it, excrete large quantities. “All mammals, with the important exception of man, are able to destroy uric acid rapidly and in considerable quantities.” This destruction is an oxidation accomplished by a specific enzyme called uricase, and the reaction seems to consist of the removal of one of the carbon atoms from the uric acid, thus converting it into the more readily soluble allantoin” (Wells). These transforming enzymes are variously distributed in the body; nuclease is present in all cells, adenase and the xanthin enzyme are not so widely distributed. Uricase, on which the uricolytic power of the different tissues depends, is present chiefly in the liver and kidneys of mammals, and to a less degree in the muscles. Man alone seems to have a difficulty in oxidizing uric acid. Even on a purin-free diet he excretes daily a certain amount, and purin-rich food is at once followed by a rise. In other mammals it is readily oxidized into allantoin, of which human urine never contains more than a trace.

Gout, then, can not be regarded as loss of the power of a given individual to destroy uric acid, since this does not appear to be an active function in the human body. Loss of power to eliminate favors the deposition of uric acid, and individuals who can not get rid easily of their purins, endogenous or exogenous, may be said to be gouty.

There is a form of gout in swine, characterized by a deposit of guanin in the muscles—the chalky flakes which are so often seen in old Virginia and Westphalian hams—and it has been found that the pig’s liver is deficient in

the enzyme *guanase*, which in other animals oxidizes this purin body. We can not say how great is the part played by uric acid in human gout and how much by the other purin bodies, but the recent tendency is to regard imperfect elimination rather than imperfect oxidation of the purin bodies as the chief factor.

The normal daily output of uric acid is from 0.4 to 1.5 gm., and it is greater by day than by night. The amount from the intake of the exogenous oxy-purins varies from 40 to 60 per cent. of the total purin content. The more active the functions of the body the greater the discharge. Severe exertion, fever and exposure to cold increase the output. The amount is greatly influenced by food, particularly when rich in purin bases; after a meal containing sweetbread the amount may be doubled. In gouty persons the output is low, and there are cases of tophaceous gout in which, in the intervals between attacks, the excretion was nil (Futcher). With the onset of an attack the output rises, and the phosphoric acid is also greatly increased (Chart XIII).

PREDISPOSING FACTORS.—*Heredity* is important. In from 50 per cent. to 75 per cent. of all cases the disease existed in the ancestors, and the transmission is more marked on the male side. Males are more subject than females. It is rarely seen before the thirtieth year, though cases have occurred before puberty, and even in infants at the breast.

Alcohol is an important factor in the etiology. Fermented liquors are more apt to cause it than distilled spirits, and the disease is more common in England and Germany, the countries which consume the largest amount of beer *per capita*. The disease is not uncommon in the United States and, as Futcher pointed out, gout is only one-third less frequent at the Johns Hopkins Hospital than at St. Bartholomew's Hospital, London. Among 18,000 patients (J. H. H.) there were 59 cases of gout; all but three in whites, and all in males but two (Futcher).

Food plays a rôle of importance and overeating without exercise is a predisposing cause. But the disease is by no means confined to the well-to-do. A combination of poor food, defective hygiene and the excessive consumption of malt liquors makes "poor man's gout" not infrequent.

Occupation is of great importance, and the disease is much more common in workers in breweries, and in persons who deal in any way with alcohol.

It is not uncommon in persons of great mental and bodily vigor. Among distinguished members of our profession who have been terrible sufferers were the elder Scaliger, Jerome Cardan and Sydenham. The statement of the latter, however, that "more wise men than fools are victims" of the affection, does not hold good to-day. The celebrated Pirckheimer wrote a famous "Apology for Gout" (1521), and there is much truth in what Podagra says: "For I take no pleasure in those hard, rough, rusticke, agresticke kind of people, who never are at rest, but always exercise their bodies with hard labors, are ever moyling and toying, do seldom or never give themselves to pleasure, do endure hunger, which are content with a slender diet." (English Edition, 1617.)

Among the direct *exciting causes* of an attack is a meal with large quantities of rich food and alcohol; worry, or a mental shock, and in sensitive persons a slight injury or accident may be followed by an acute attack.

Pathology.—The *blood* contains an excess of uric acid. The average amount in 156 non-gouty patients was 1.7 mgs. per 100 c. c. of blood with variations from 0.7 to 4.5 mgs. (Adler and Ragle). Pratt's studies in 21 gouty patients showed an average of 3.7 mgs. per 100 c. c. of blood. The high

CHART XIII.—URIC ACID AND PHOSPHORIC ACID OUTPUT IN CASE OF ACUTE GOUT.

uric acid content is generally constant in gout and the amount is apparently greater during an attack than in the intervals. This excess is not peculiar to gout, but occurs in leukæmia and severe nephritis. The red cells in the "lead-gout" cases may show basophilic granular staining.

The important changes are in the articular tissues. The first joint of the

great toe is most frequently involved; then the ankles, knees, and the small joints of the hands and wrists. The deposits may be in all the joints of the lower limbs and absent from those of the upper limbs (Norman Moore). If death takes place during an acute paroxysm, there are signs of inflammation, hyperæmia, swelling of the ligamentous tissues, and of effusion into the joint. The primary change, according to Ebstein, is a local necrosis, due to the presence of an excess of urates in the blood. This is seen in the cartilage and other articular tissues in which the nutritional currents are slow. The excess of uric acid in the serum may act as a potential exciting cause capable of determining a local reaction, with urate deposit, when some provocative agent is associated. The articular cartilages are first involved with the gouty deposit uniform or in small areas. Though it looks superficial, the deposit is invariably interstitial and covered by a thin lamina of cartilage. The deposit is thickest at the part most distant from the circulation. The ligaments and fibro-cartilage ultimately become involved and are infiltrated with urate deposits, the so-called chalk-stones, or tophi. These are usually covered by skin; but in some cases, particularly in the metacarpo-phalangeal articulations, this ulcerates and the chalk-stones appear externally. The synovial fluid may also contain crystals. In long-standing cases, owing to an excessive deposit, the joint becomes immobile. The marginal outgrowths in gouty arthritis are true exostoses (Wynne). The cartilage of the ear may contain tophi, which are seen as whitish nodules at the margin of the helix. The cartilages of the nose, eyelids, and larynx are less frequently affected.

The changes in the renal and vascular systems are important. The kidney changes believed to be characteristic of gout are: (a) A deposit of urates chiefly in the region of the papillæ but this is less common than is usually supposed. Norman Moore found it in only 12 of 80 cases. The apices of the pyramids show lines of whitish deposit. Ebstein described areas of necrosis in both cortex and medulla, in which were crystalline deposits of urate of soda. (b) An interstitial nephritis, either the ordinary "contracted kidney" or the arterio-sclerotic form, neither of which is in any way distinctive. (c) Arterio-sclerosis and cardiac hypertrophy are frequent lesions. Concretions of urate of soda may occur on the valves. Myocarditis is common.

Changes in the respiratory system are rare. Deposits have been found in the vocal cords, and uric-acid crystals have been found in the sputum of a gouty patient (J. W. Moore).

Symptoms.—Gout is divided into acute, chronic, and irregular forms.

ACUTE GOUT.—Premonitory symptoms are common—twinges of pain in the small joints of the hands or feet, nocturnal restlessness, irritability of temper, and dyspepsia. The urine is acid, scanty and high-colored and there may be transient albuminuria. There may be traces of sugar (gouty glycosuria). Before an attack the output of uric acid is low and is also diminished in the early part of the paroxysm. The relation of uric and phosphoric acids to the acute attacks is represented in Chart XIII, prepared by Fletcher. Both may be extremely low in the intervals, but reach normal limits shortly after the onset of the acute symptoms. The phosphoric acid and uric acid show almost parallel curves. The patient was on a very light fixed diet at the time the determinations were made. In some instances the throat is sore, and there may be dyspnoea. The attack sets in usually in the early morning hours.

The patient is aroused by a severe pain in the metatarso-phalangeal articulation of the big toe, and more commonly on the right than on the left side. The tarsus is often involved, sometimes alone. The pain is agonizing, and, as Sydenham says, "insinuates itself with the most exquisite cruelty among the numerous small bones of the tarsus and metatarsus, in the ligaments of which it is lurking." The joint swells rapidly, and becomes hot, tense, and shiny. The sensitiveness is extreme, and the pain makes the patient feel as if the joint were being pressed in a vice. There is fever, and the temperature may rise to 102° to 103° F. Toward morning the severity of the symptoms subsides, and, although the joint remains swollen, the day may be passed in comparative comfort. The symptoms recur the next night, and the "fit," as it is called, usually lasts for from five to eight days, the severity of the symptoms gradually abating. There is usually a polynuclear leucocytosis during the acute manifestations. Other joints may be involved, particularly the tarsal joints. The inflammation, however intense, never goes on to suppuration. With the subsidence of the swelling the skin desquamates. After the attack the general health may be much improved. As Aretæus remarks, a person in the interval has won the race at the Olympian games. Recurrences are frequent. Some patients have three or four attacks in a year; others suffer at longer intervals.

The term *retrocedent or suppressed gout* is applied to serious internal symptoms, coincident with a rapid disappearance or improvement of the local signs. Very remarkable manifestations may occur. The patient may have severe gastro-intestinal symptoms—pain, vomiting, diarrhoea, and great depression—and death may occur during such an attack. Or there may be cardiac manifestations—dyspnoea, pain, and irregular action. In some instances an acute pericarditis proves fatal. So, too, there may be marked cerebral manifestations—delirium or coma, and even apoplexy—but in a majority of these instances the symptoms are, in all probability, uræmic.

CHRONIC GOUT.—With increased frequency in the attacks, the articular symptoms persist for a longer time, and gradually many joints become affected. Deposits of urates take place, at first in the articular cartilages and then in the ligaments and capsular tissues; so that in the course of years the joints become swollen, irregular, and deformed. The feet are usually first affected, then the hands. In severe cases there may be extensive concretions about the elbows and knees and along the tendons and in the bursæ. Bursitis is fairly common. The tophi appear in the ears. Finally, a unique clinical picture is produced which can not be mistaken for that of any other affection. The skin over the tophi may rupture or ulcerate, and about the knuckles the chalk-stones may be freely exposed. Patients with chronic gout are usually dyspeptic, often of a sallow complexion, and have arterio-sclerosis. The blood pressure is increased, the vessels are stiff, and the left ventricle is hypertrophied. The urine is increased in amount, of low specific gravity, and usually contains a slight amount of albumin with a few hyaline casts. Severe cramps involving the calf, abdominal, and thoracic muscles are common. Intercurrent attacks of acute polyarthritis may occur, in which the joints become inflamed, and the temperature ranges from 101° to 103° F. There may be pain, redness, and swelling of several joints without fever. Uræmia,

pleurisy, pericarditis, peritonitis, and meningitis are common terminal affections.

IRREGULAR GOUT.—This is a motley, ill-defined group of symptoms, manifestations of disordered nutrition, to which the term *gouty diathesis* has been given. Cases are seen in members of gouty families, who may never themselves have suffered from the acute disease, and in persons who have lived not wisely but too well, who have eaten and drunk largely, lived sedentary lives, and yet have been fortunate enough to escape an acute attack. It is interesting to note the various manifestations in a family with marked hereditary disposition. The daughters often escape, while one son may have gouty attacks of great severity, even though he lives a temperate life and tries in every way to avoid the conditions favoring the disorder. Another son has, perhaps, only the irregular manifestations and never acute arthritis. While the irregular features are perhaps more common in the hereditary form, they are by no means infrequent in persons who appear to have acquired the disease. The tendency in some families is to call every affection gouty. Even infantile complaints, such as eczema, naso-pharyngeal vegetations, and enuresis, are often regarded, without sufficient grounds, as evidences of the family ailment. Among the manifestations of irregular gout are the following:

(a) *Cutaneous Eruptions*.—Garrod and others have called special attention to the frequent association of eczema with the gouty habit.

(b) *Gastro-intestinal Disorders*.—Attacks of what is termed “biliousness,” in which the tongue is furred, the breath foul, and the bowels constipated, are not uncommon in gouty persons. A gouty parotitis is described.

(c) *Cardio-vascular Symptoms*.—With gout arterio-sclerosis is frequently associated. The blood pressure is high, the vessel walls become stiff, and cardiac and renal changes gradually occur. In this condition the symptoms may be renal and dropsical features supervene. The manifestations may be cardiac, when the left ventricle fails or they may be vascular, and thrombosis of the coronary arteries may cause sudden death, or, as most frequently happens, cerebral hæmorrhage occurs. It makes but little difference whether we regard this condition as primarily an arterio-sclerosis or a nephritis; the point to be remembered is that the nutritional disorder with which an excess of uric acid is associated induces in time increased tension, arterio-sclerosis, chronic nephritis, and changes in the myocardium. Pericarditis is not an infrequent terminal complication. Phlebitis is a troublesome and not very uncommon complication. It may arise in connection with varicose veins of the legs or occur in many venous districts in succession or simultaneously.

(d) *Nervous Manifestations*.—Headache, migraine attacks, neuralgias, sciatica, and paræsthesias are not uncommon. A common gouty manifestation, upon which Duckworth has laid stress, is the occurrence of hot or itching feet at night. Plutarch mentions that Strabo called this “the lisp of the gout.” Cramps in the legs may be very troublesome. Hutchinson called attention to hot and itching eyeballs. Associated or alternating with this symptom there may be attacks of episcleral congestion. Apoplexy is a common termination and meningitis may occur, usually basilar.

(e) *Urinary Disorders*.—The urine is acid and high colored, and may deposit crystals of uric acid on standing. In many cases of chronic gout the

amount of uric acid is diminished, and increased only at certain periods, forming the so-called uric-acid showers. A sediment of uric acid in a urine does not necessarily mean an excess. It is often dependent on the inability of the urine to hold it in solution. Sugar is found occasionally in the urine of gouty persons—gouty glycosuria. It may pass into true diabetes, but is usually very amenable to treatment. Oxaluria may also be present. Gouty persons are specially prone to calculi, Jerome Cardan to the contrary, who reckoned freedom from stone among the chief of the *dona podagræ*. Small quantities of albumin and casts are common. Urethritis, with a purulent discharge, may arise, so it is stated, usually at the end of an attack. It may occur spontaneously, or follow a pure connection.

(f) *Pulmonary Disorders.*—There are no characteristic changes, but chronic bronchitis occurs with great frequency in persons of a gouty habit.

(g) Of eye affections, iritis, glaucoma, hæmorrhagic retinitis, and suppurative panophthalmitis have been described.

X-rays.—The changes in the bones, which are not typical but only suggestive, consist of small dark areas on the plates, circular in outline, with clear, sharp borders. They are usually found in the epiphysis of the affected joints, especially of the fingers, and are due to the absorption of calcium in areas in which sodium urate has been deposited.

Diagnosis.—Recurring attacks of arthritis, limited to the big toe or to the tarsus, occurring in a member of a gouty family, or in a man who has lived too well, leave no question as to the nature of the trouble. There are many cases of gout, however, in which the feet do not suffer most severely. After an attack or two in one toe, other joints may be affected, and it is just in such cases of polyarthritis that the difficulty in diagnosis is apt to arise. The presence of tophi may settle the nature of an arthritis which in the previous attacks has been regarded as rheumatic. The following are suggestive points: (1) The patient's habits and occupation. Workers in breweries and barkeepers are often affected. (2) The presence of tophi. The ears should always be inspected in a case of polyarthritis. The diagnosis may rest with a small tophus. The student should learn to recognize, on the ear margin, Woolner's tip, fibroid nodules, and small sebaceous tumors. The last are easily recognized microscopically. The needle-shaped sodium urate crystals are distinctive of the tophi. (3) The urine. The uric-acid output is usually very low during the intervals and at the height of the attack the elimination, as a rule, is greatly increased. (4) The amount of uric-acid in the blood. If this is increased above normal limits constantly, leukæmia and nephritis being excluded, it is important evidence. The gouty polyarthritis may be afebrile. A patient with several red, swollen and painful joints in rheumatic fever has pyrexia, and, while it may be present and often is in gout, its absence is a valuable sign. Many cases go a-begging for a diagnosis. A careful study of the patient's habits as to beer drinking, of the location of the initial arthritic attacks, and the examination for tophi and bursitis will prevent many cases being mistaken for rheumatic fever or arthritis deformans. Lastly, in doubtful forms of arthritis a careful study of the purin metabolism is of value.

Prognosis.—"Once gouty, always gouty" is usually true, but by care the frequency and intensity of attacks can be reduced. As regards the

duration of life, the state of the circulation and kidneys is the important factor.

Treatment.—**HYGIENIC.**—Individuals with gout should live temperately, abstain from alcohol, and eat moderately. The bowels should be kept open. An open-air life, with plenty of exercise and regular hours, does much to counteract an inborn tendency to the disease. The skin should be kept active and an occasional Turkish bath is advantageous. The patient should dress warmly, avoid rapid alterations in temperature, and be careful to avoid sudden chilling.

DIETETIC.—With few exceptions, persons over forty eat too much, and the first injunction to a gouty person is to keep his appetite within reasonable bounds, to eat at stated hours, and to take plenty of time at his meals. In the matter of food, quantity is a factor of more importance than quality with many gouty persons. As Sir William Roberts well says, "Nowhere perhaps is it more necessary than in gout to consider the man as well as the ailment, and very often more the man than the ailment."

The weight of opinion leans to a modified nitrogenous diet, without excess in starchy and saccharine foods. In some patients restriction of carbohydrates is important. Foods rich in purins, such as bouillon, beef extracts, sweet-breads, liver, kidneys, and brain, should be avoided. Milk and eggs are particularly useful, owing to their being purin free. Fresh vegetables and fruits may be used freely but strawberries and bananas should be avoided.

Ebstein urged strongly the use of fat in the form of fresh butter, from $2\frac{1}{2}$ to $3\frac{1}{2}$ ounces in the day. He held that stout gouty subjects not only do not increase in weight with plenty of fat in the food, but that they lose weight and the general condition improves. Hot bread of all sorts and the articles of food prepared from Indian corn should, as a rule, be avoided. Roberts advised gouty patients to restrict as far as practicable the use of common salt, since the sodium urate very readily crystallizes out in tissues with a high percentage of sodium salts. In this matter of diet each individual must receive separate consideration.

Alcohol in any form is harmful; if some must be taken whisky is the least injurious. Some forms are especially harmful, particularly malted liquors, champagne, port, and a large proportion of all the light wines.

MINERAL WATERS.—All forms may be said to be beneficial in gout, as the main element is the water, and the ingredients are usually indifferent. Much of the humbuggery in the profession still lingers about mineral waters, more particularly about the so-called lithia waters.

The question of the utility of *alkalies* in the treatment of gout is closely connected with this subject of mineral waters. This deep-rooted belief was shaken by Sir William Roberts, who claimed that alkalescence as such has no influence whatever on the sodium urate and that the sodium salts are particularly harmful. In spite of the theoretical denunciation of the use of sodium salts, the gouty from all parts of the world flock to those very Continental springs in which these salts are most predominant. Of the mineral springs best suited for the gouty may be mentioned, in the United States, those of Saratoga, Bedford, and the White Sulphur; Buxton and Bath, in England; in France, Aix-les-Bains and Contrexeville. Excellent results are claimed for mineral waters with special radio-active properties. The efficacy

in reality is in the water, in the way it is taken, on an empty stomach, and in large quantities; and the important accessories in the modified diet, proper hours, regular exercises, with baths, douches, etc., play a very important rôle.

MEDICAL TREATMENT.—In an acute attack the patient should be at rest, on a milk diet, and take water freely. The limb should be elevated and the affected joint wrapped in cotton-wool. Warm fomentations or Fuller's lotion may be used. The local hot-air or passive hyperæmia treatment may be tried. A brisk mercurial purge is always advantageous at the outset. The wine or tincture of colchicum, in doses of 20 to 30 minims (1.2 to 2 c. c.) may be given every four hours with citrate of potassium. The action of the colchicum should be carefully watched; its effect is most marked when free purgation follows. It has in a majority of the cases a powerful influence over the symptoms—relieving the pain, and reducing, sometimes with great rapidity, the swelling and redness. It should be stopped as soon as the pain is relieved. Phenylquinolin (cinchophen, atophan) is more useful in subacute attacks and chronic conditions than in acute attacks. The dosage is 10 to 15 grains (0.6-1 gm.) three or four times a day. It is sometimes useful in smaller doses (0.5 gm.) given on two days each week as a preventive. It increases the excretion of uric acid. In cases in which the pain and sleeplessness are distressing and do not yield to treatment, morphia is necessary. During convalescence the diet should be increased slowly.

In some acute and subacute attacks sodium salicylate or acetyl-salicylic acid may be useful. The chronic and irregular forms are best treated by dietetic and hygienic measures. Potassium iodide is sometimes useful. Albu speaks favorably of lemon-juice as a remedy. The vegetable acids are converted in the system into alkaline carbonates, enabling the blood to keep the uric acid compounds in solution, and facilitating their elimination.

Where the arthritic attacks are confined to the great toe joint, surgical interference may be considered. Riedel reports cases in which he removed the entire joint capsule of the big-toe joint, with permanent relief.

II. DIABETES MELLITUS

Definition.—A disease of metabolism, especially of the carbohydrates, in which the normal utilization of carbohydrate is impaired with an increase in the sugar content of the blood and consequent glycosuria. There is a tendency to subsequent disturbance of the fat metabolism with resulting ketosis.

History.—The disease was known to Celsus. Aretæus first used the term diabetes, calling it a wonderful affection "melting down the flesh and limbs into urine." He suggested that the disease got its name from the Greek word signifying a syphon. Willis in the seventeenth century gave a good description and recognized the sweetness of the urine "as if there has been sugar and honey in it." Dobson in 1776 demonstrated the presence of sugar, and Rollo in 1797 wrote an admirable account and recommended the use of a meat diet. The modern study of the disease dates from Claude Bernard's demonstration of the glycogenic function of the liver in 1857.

Etiology.—The enzymes of the intestinal mucosa convert the starches and

sugars of the food into monosaccharides—dextrose, galactose and levulose—which pass into the portal circulation, but the major portion remains in the liver, where it is converted into glycogen. The percentage of sugar in the systemic blood remains constant—0.08 to 0.12 per cent. Part of the sugar passes to the muscles, where it is stored as glycogen. The total storage capacity of the liver is estimated at about one-tenth of its weight, i. e., about 150 gms. for an ordinary organ weighing 1,500 gms.

Glucose is also derived from protein, of which 58 per cent. is converted into glucose, and from fat, of which 10 per cent. is converted into glucose. This applies both to exogenous and endogenous protein and fat.

The following conditions influence the appearance of sugar in the urine:

(a) CARBOHYDRATE INTAKE.—Normally the blood sugar is from 0.08 to 0.12 per cent. An intake of 100 grams of dextrose causes a rise to about 0.18 per cent. This reaches its maximum ordinarily in about thirty minutes after ingestion and then in about ninety minutes falls to the normal figure. The percentage and times vary in different individuals. In normal individuals this does not result in the appearance of sugar in the urine but again we find great variation depending on the renal threshold for sugar ("the leak point"). The kidney cells excrete sugar at different concentrations in the blood, in one at 0.15 per cent. and in another at 0.2 per cent. In diabetes the percentage is usually from 0.2 to 0.4 per cent. Like the balance at the Mint, which is sensitive to the correct weight of the gold coins passing over it, the renal cells only react at a certain point of saturation. There is no constant relation between the amount of sugar in the blood and that in the urine, although the figures are often comparative. There may be a high blood sugar and a small amount in the urine. The renal threshold for sugar seems to rise as age increases, so in old persons it is specially important to know the amount of blood sugar. It rises also in nephritis.

(b) NERVOUS SYSTEM.—Bernard showed that there was an area in the medulla puncture of which is followed by hyperglycemia due to an increased outflow of sugar from the liver. He demonstrated that the efferent path of this influence was through the splanchnic nerves and the afferent through the vagi. Many lesions of the nervous system cause glycosuria—tumors, particularly those in the neighborhood of the medulla, injuries to the brain and to the upper part of the spinal cord, meningitis, and hemorrhage. These probably disturb the internal secretion of the hypophysis. Clinically, glycosuria arising from organic disturbances in the nervous system is not important.

The influence of *functional nervous disturbance* is difficult to estimate. There does not seem proof that this may be the sole primary factor but there is no doubt that, once established, diabetes mellitus is influenced by the general state of the nervous system. Worry, mental strain, anxiety, etc., may have a marked influence. Severe nervous strain may cause temporary glycosuria possibly through increased action of the adrenal glands.

(c) INTERNAL SECRETIONS.—Four of the glands of internal secretion influence the amount of sugar in the blood. Of these the pancreas (islands of Langerhans) is the most important and is alone in its action, being opposed by the suprarenal, thyroid and pituitary (posterior lobe) glands. Over-

activity of these three glands tends to cause glycosuria; under-activity increased sugar tolerance. Under-activity of the pancreas (internal secretion) results in hyperglycæmia and glycosuria. There may be a condition of hypoglycæmia due to overproduction of insulin.

(1) *Pancreas*.—The only way in which diabetes mellitus can be produced experimentally is by removal of the pancreas. This results from lack of the internal secretion, derived from the islands of Langerhans, which is necessary for carbohydrate metabolism. The essential factor in diabetes mellitus is a disturbance of this function of the pancreas. The cells of the islands of Langerhans contain specific granules (Bensley) which disappear if overworked by excessive carbohydrate intake. Many diseases of the pancreas are associated with glycosuria, some with permanent diabetes. Hæmorrhagic pancreatitis, cancer, calculus and chronic interstitial pancreatitis may all be associated with disturbance in the carbohydrate metabolism. The islands of Langerhans have the ability to produce increased amounts of secretion (insulin) when this is required. But it is not clear how insulin acts. One view is that it aids the oxidation of glucose but there is no evidence that there is interference with the oxidation of glucose in the muscles in diabetes. The increase in metabolism in diabetes by insulin may be due to its action on the glycosuria in the blood enabling it to be used or to be converted to glycogen.

(2) *Hypophysis*.—It was long known that glycosuria occurred in tumors of the region of the hypophysis, particularly in acromegaly, and it follows fractures of the base of the skull. Experimentally, Cushing and his students have shown that the posterior lobe of the pituitary gland has an important influence in carbohydrate metabolism. Any operative disturbance of it, or of the infundibulum, is followed by glycosuria, and by a remarkable lowering of the carbohydrate tolerance. On the other hand, a deficiency of this secretion, or the removal of this portion of the gland alone, is followed by a remarkable increased tolerance for carbohydrates.

A tumor which at first irritates the gland, as in the early stages of acromegaly, may cause glycosuria, but later, as the posterior lobe of the gland is destroyed, there is an extraordinarily high carbohydrate tolerance, and associated with it a great increase in the deposition of fat in the body, a syndrome to be referred to later. The extract of the posterior lobe causes a decrease in sugar tolerance.

(3) *Adrenals and Thyroids*.—Glycosuria does not necessarily follow lesions of the adrenals, but epinephrine has a powerful influence on the carbohydrate metabolism, and glycosuria may be readily produced in animals by subcutaneous injection and by the local application of epinephrine to the pancreas. Clinically, we know practically nothing of an adrenal glycosuria. It has occasionally been noticed in the prolonged therapeutic use of epinephrine. Puncture of the floor of the fourth ventricle does not cause glycosuria after removal of the adrenal glands. The influence of the adrenal secretion is antagonistic to that of the pancreas. In disturbances of the thyroid gland glycosuria is not uncommon. The use of thyroid extract is occasionally followed by glycosuria. Hyperthyroidism and glycosuria are often associated, and the hyperthyroid patient is more prone to diabetes for the rest of life. In myxedema the carbohydrate tolerance may be increased.

The glycosuria associated with pregnancy may be due to disturbance of

the internal secretions. It is transient, usually disappearing with parturition, and rarely leads to diabetes. It may recur in successive pregnancies.

(d) LIVER FUNCTION.—A most remarkable feature in carbohydrate metabolism is that the great warehouse of the sugars may be damaged to any degree without causing hyperglycæmia or glycosuria. Whether there is a form of disease to which the name "liver diabetes" may be given is doubtful. There are cases of cirrhosis of the liver and of gall-stones—particularly those with enlargement of the organ—in which glycosuria is present, but they are probably all associated with coincident affections of the pancreas. In hæmochromatosis, which is accompanied by great enlargement of the liver, the glycosuria is probably pancreatic.

(e) RENAL FUNCTION.—Disease of the kidneys is rarely associated with glycosuria. Occasionally one finds it and often increased blood sugar in chronic nephritis, but a true diabetes depending upon renal changes is not proved. There is a remarkable experimental diabetes of great interest in connection with carbohydrate metabolism. If phloridzin, a glucoside prepared from the bark of the apple-tree, is given by mouth or subcutaneously to man or animals glycosuria results, and even continues on a nitrogenous diet, and in man when fasting. The glycosuria may be marked, yet there is no hyperglycæmia. In the condition termed "renal glycosuria," in which the blood sugar is normal but the kidney threshold for sugar is low, there may be glycosuria but this is not diabetes mellitus.

(f) OBESITY.—Joslin has specially emphasized the importance of overweight in the etiology, especially in adult and mature life.

(g) MISCELLANEOUS DISTURBANCES.—The carbohydrate metabolism may be upset in acute fevers and a transient glycosuria appears. In septic conditions, sometimes with carbuncle, glycosuria may occur as a *secondary* phenomenon and disappear after recovery. It is not uncommon after the administration of ether, less so after chloroform. Metabolic disturbances in gout may be associated with glycosuria, and cachexias and profound anæmias may be accompanied by transient glycosuria. There are patients, usually with marked arterio-sclerosis, in whom there is apparently no lack of insulin and hence no response to its administration. The difficulty seems to be in the utilization of sugar in some way apart from lack of insulin. Patients suffocated by smoke or poisoned by coal gas may have sugar in the urine. Syphilis does not seem to play a marked rôle.

INCIDENCE.—The disease is on the increase in many countries, due probably to over-nutrition, especially from a large consumption of sugar, and less exercise, in which the motor car plays a large part. In England and Wales the deaths increased from 2,767 in 1902 to 4,542 in 1916. There were 5,180 deaths in 1928. In the United States the statistics for 1870 gave 2.1; for 1890, 3.8; for 1900, 9.3; and for 1915, 17.5 deaths to 100,000 population. The rate for 1925 is 16.9.

HEREDITARY INFLUENCES play an important rôle and the disease may occur in many members of the same family. Morton, who calls the disease *hydrops ad matulan* (Phthisiologia, 1689), records a family in which four children were affected, one of which recovered on a milk diet and diascordium. The family dietary and obesity are factors in this. There are instances of the coexistence of the disease in man and wife. Among 516 married pairs

collected by Senator, in which either husband or wife was diabetic, in 18 cases the second partner had become diabetic. Similarity in habits probably accounts for this.

SEX AND AGE.—There has been an increase in the number of cases in women. In Joslin's series, of 2,440 cases from 1898 to 1922, 45 per cent. were females, but of 2,646 cases from 1922 to 1927, 55 per cent. were females. It is a disease of adult life; a majority of the cases occur from the third to the sixth decade. About 50 per cent. of the cases occur between the ages of 40 and 60.

DIABETES IN CHILDREN.—This usually occurs among the better classes. Hereditary influences are marked. While the disease is usually severe there are not infrequent cases of a mild type. One case is mentioned of a child apparently born with glycosuria, who recovered in eight months.

Persons of a neurotic *temperament* are often affected. It is a disease of the higher classes. Van Noorden states that the statistics for London and Berlin show that the number of cases in the upper ten thousand exceeds that in the lower hundred thousand inhabitants.

RACE.—Hebrews seem especially prone to it; one-fourth of Frerichs' patients were of the Semitic race. Diabetes is comparatively rare in the colored race, but not so uncommon as was formerly supposed. Of the series of 276 cases, 29, or 10.6 per cent., were in negroes.

Metabolism in Diabetes.—Glycosuria may be a matter of simple overflow of sugar over the renal threshold, but the essence of true diabetes is a waste of the carbohydrates, which hurry through the body, in great part never warehoused as glycogen. It is suggested that there is a difference in the form of glucose in the normal person and in the diabetic. The result is a failure of the normal oxidation of the carbohydrates. The polyuria is a result of the diuretic action of the sugar which requires considerable water to carry it off. The thirst is a result of the polyuria. There is a very considerable daily loss of energy in warming the liquids taken to the temperature of the body, according to Benedict and Joslin nearly 6 per cent. of the total heat of the day. The excess of sugar renders the body a favorable culture medium for pus organisms. There is loss of energy with the steady waste of sugar; practically every gram of sugar excreted in the urine results in a loss of 4.1 calories, consequently a diabetic patient excreting 100 grams of sugar and 20 grams of β -oxybutyric acid loses 500 calories in this way, so that the patients are underfed, unless this loss is made up by other food (Benedict and Joslin). Studies upon the respiratory quotient—which is the ratio between the CO_2 given out and the O taken in by a healthy individual on a mixed diet (expressed by the fraction (0.9)—favor the view that there is failure in the proper combustion of the carbohydrates. Benedict and Joslin conclude that a respiratory quotient above 0.74 indicates a fairly liberal supply of glycogen stored in the body; while a respiratory quotient of 0.70, or below that, indicates that the patient has no available carbohydrates, and has lost in a measure the power of storing them. Here comes the special danger; as the carbohydrates pass through the body unburned, the energy must be provided from protein and fat. The metabolism of the former does not appear to be seriously disturbed, and the carbohydrate portion of the protein molecule in part supplies the place of the lost sugars. The danger is in the metabolism

of the fats. The carbohydrates are not used as fuel; the proteins are easily utilized, but apparently it takes so much draught to burn them that not enough is left to consume the fats completely; and the products of incomplete combustion accumulate and suffocate the patient as effectually as does the CO of a charcoal stove. The chief products of this incomplete combustion of the fats are β -oxybutyric acid, diacetic acid and acetone, and the special danger of the disease is the production of ketosis.

The CO₂ tension of the alveolar air is reduced. In slight acidosis this is between 32 and 38 mm. Hg, in moderate acidosis 28 to 32 mm. Hg, and in severe acidosis less than 28 mm. Hg (normal 38-45 mm. Hg). The lowest figure noted by Joslin was 9 mm. Hg.

Lipæmia.—The blood contains an excess of fat in severe cases; fat, lecithin and cholesterol may all be increased. In *lipæmia retinalis* the vessels are white against a pink background. This may be due to a film of fatty lymph in the perivascular spaces or to fat deposits in the adventitia.

Renal Glycosuria.—This is a better term than renal diabetes to designate a condition in which there is glycosuria without increase of the sugar in the blood. In it the glycosuria is independent of the carbohydrate intake and the blood sugar is normal or decreased in amount. The kidney threshold for sugar is low. As a rule it is discovered accidentally as there are rarely any symptoms. In some cases exercise immediately after meals prevents the glycosuria and removal of infected tonsils has influenced it (Schneiderman). The condition is rare and the patients should be followed for a long time to exclude Diabetes Mellitus.

Morbid Anatomy.—The *nervous system* shows no constant lesions. In a few instances there have been tumors or sclerosis in the medulla, or a cysticercus has pressed on the floor. A secondary multiple neuritis is not rare and changes occur in the posterior columns of the cord similar to those found in pernicious anæmia. In the sympathetic system the ganglia have been enlarged and in some instances sclerosed. The *heart* is hypertrophied in some cases. Endocarditis is very rare. *Arterio-sclerosis* is common. The *lungs* show important changes. Acute broncho-pneumonia or lobar pneumonia (either of which may terminate in gangrene) and tuberculosis are common. In rare cases there is a chronic fibroid pneumonia. Fat embolism of the pulmonary vessels may occur with diabetic coma.

The *liver* is usually enlarged; fatty degeneration is common. In the so-called diabetic cirrhosis—the *cirrhosis pigmentaire*—the liver is enlarged and sclerotic, and cachexia develops with melanoderma. Dilatation of the stomach with enlargement of the duodenum and colonic stasis are common.

Pancreas.—There are no macroscopic changes. Histologically there may be chronic interstitial fibrosis and hydropic degeneration. In the *islands of Langerhans* the specific granules are absent and the cells show changes.

The *kidneys* show a diffuse nephritis with fatty degeneration. Hyaline change is frequently found in the tubal epithelium as well as in the Malpighian tufts.

Symptoms.—*Acute* and *chronic* forms are recognized, but there is no essential difference between them, except that in the former the patients are, as a rule, younger, the course is more rapid, and the emaciation is usually more marked.

The *onset* is gradual, and either frequent micturition or inordinate thirst first attracts attention. The glycosuria is often discovered in an insurance or routine examination. Very rarely it sets in rapidly, after a sudden emotion, an injury, or after a severe chill. When fully established the disease is characterized by great thirst, the passage of large quantities of saccharine urine, a voracious appetite, and, as a rule, progressive emaciation.

Among the GENERAL SYMPTOMS *thirst* is one of the most distressing. Large quantities of water are required to keep the sugar in solution and for its excretion in the urine. The amount of fluid intake bears a definite ratio to the quantity excreted. Instances, however, are not uncommon in which the thirst is not excessive; but in such cases the amount of urine is never large. The thirst is most intense an hour or two after meals. As a rule, the digestion is good and the appetite may be inordinate. *Lumbar pain is common.*

The tongue is usually dry, red, and glazed, and the saliva scanty. The gums may become swollen, and in the later stages aphthous stomatitis is common. Constipation is the rule.

In spite of a large intake of food a patient may become rapidly emaciated. This loss of flesh bears some ratio to the polyuria, and when the sugar is reduced, the patient may gain in flesh. The skin is dry and harsh, and sweating rarely occurs, except when tuberculosis coexists. Drenching sweats have been known to alternate with excessive polyuria. General *pruritus* or pruritus pudendi may be very distressing, and occasionally is one of the earliest symptoms. The temperature is often subnormal; the pulse is usually frequent, and the tension increased. Many diabetics do not show marked emaciation. Patients past the middle period of life may have the disease for years without much disturbance of the health, and may remain well nourished.

URINE.—The amount varies from 3 to 4 litres in mild cases to 15 to 20 litres in very severe cases. In rare instances the quantity is not much increased. Under treatment the amount is much lessened, and in intercurrent febrile affections it may be reduced to normal. The *specific gravity* is high, ranging from 1.025 to 1.045; but in exceptional cases it may be low, 1.013 to 1.020. The highest specific gravity recorded is by Trousseau—1.074. Very high specific gravities—over 1.070—suggest fraud. The urine is pale in color, almost like water, and has a sweetish odor and taste. Sugar is present in varying amounts. In mild cases it does not exceed $1\frac{1}{2}$ or 2 per cent., but it may reach from 5 to 10 per cent. The total amount excreted in twenty-four hours may be 10 to 20 ounces (320 to 640 grams) and in exceptional cases 1 to 2 pounds.

Ketonuria.—The ketone bodies, acetone, diacetic acid and β -oxybutyric acid are present, sometimes in small amounts in mild cases but increasing with the severity of the disease; and are indications of ketosis. In coma the excretion of β -oxybutyric acid may be as much as 100 gm. or more a day.

Glycogen has been found in the urine, and in rare instances sugars other than glucose occur, lactose, levulose, and pentose, and to these conditions the term *melituria* is sometimes applied. *Albumin* is not infrequent.

Pneumaturia, gas in the urine, due to fermentation in the bladder, is occasionally met with. Fat may be passed in the urine in the form of a fine emulsion (*lipuria*).

BLOOD.—Polycythæmia may be present to 6 or 8 millions of red cells per

comm. Towards the end and with complications there may be a leucocytosis and the leucocytes may contain glycogen. The blood sugar is rarely above 0.4 per cent. The increase in the blood sugar may persist after glycosuria has disappeared.

The alkalinity is lessened and the specific gravity reduced. *Lipæmia* is present in many cases. The blood lipoids are increased from the normal figure of about 0.6 per cent. to 0.83 per cent. in mild cases, to 0.9 in moderately severe and 1.4 per cent. in severe cases (Joslin). *Lipæmia* may be present without ketosis.

Complications.—(a) *COMA (Ketosis)*.—In the typical dyspnœic coma, the air-hunger of Kussmaul, there are loud and deep in- and expirations and the breath very often has the fruity odor of acetone. It may come on without any premonition and the patient may waken out of sleep in dyspnœa. An acyanotic dyspnœa is one of the best indications of ketosis. *Dyspepsia*, constipation, abdominal pain, marked irritability and restlessness may precede the onset of coma and should suggest its possibility. Other features are marked signs of dehydration, a soft eyeball, probably due to lowered intra-ocular tension, low blood pressure, a marked reduction in the carbon dioxide of the alveolar air and occasionally convulsions. There may be a marked leucocytosis (with a normal differential count) which may suggest an acute inflammatory abdominal condition, especially if there is abdominal pain.

Difficulty may arise in the diagnosis of coma from insulin shock (hypoglycæmia) especially without a clear history. The blood sugar estimation is important, but takes time and may not be possible. The soft eyeball in coma and a low temperature, usually below 97° F., in insulin shock are important. An extensor plantar response has been obtained in hypoglycæmic coma. Some patients present a form of coma which is not typical diabetic coma; the blood sugar may be normal or nearly so without ketonuria or glycosuria, yet coma persists. There may be features suggestive of uræmia but there is no marked nitrogen retention. Death usually follows.

(b) *CUTANEOUS*.—Boils and carbuncles are common and painful onychia may occur. Eczema is also met with, and at times an intolerable itching. In women there may be the most intense pruritus pudendi, and in men a balanitis. Rarer affections are xanthoma and purpura. *Gangrene* is not uncommon, and is associated usually with arterio-sclerosis. Perforating ulcer of the foot occurred in 7 of 276 cases. Bronzing of the skin (*diabète bronzé*) occurs in *hæmochromatosis*. Profuse sweats may occur.

(c) *PULMONARY*.—The patients are not infrequently carried off by *acute pneumonia*, which may be lobar or lobular. *Gangrene* is apt to supervene but the breath does not necessarily have the foul odor of ordinary gangrene. Abscess following lobar pneumonia occurred in one of our cases. *Tuberculous broncho-pneumonia* is common and may run a rapid course.

(d) *RENAL*.—*Albuminuria* is tolerably frequent. The amount varies greatly, and, when slight, is not of much moment. Œdema of the feet and ankles is not infrequent but general anasarca is rare, owing to the marked polyuria. It occasionally precedes the occurrence of diabetic coma. Marked œdema may occur apart from renal disease; sometimes it is due to large doses of sodium bicarbonate in which case it is decreased by giving potassium bicarbonate. Occasionally cystitis is a troublesome symptom.

(e) **NERVOUS SYSTEM.**—*Peripheral Neuritis.*—Neuralgia, numbness and tingling, uncommon symptoms in diabetes, are probably minor neuritic manifestations. The involvement may be general of the upper and lower extremities. Sometimes it is unilateral, or the neuritis may be in a single nerve—the sciatic or the third nerve. Herpes zoster may occur. The so-called “*diabetic tabes*” is a peripheral neuritis, characterized by lightning pains in the legs, loss of knee-jerk—which may occur without the other symptoms—and a loss of power in the extensors of the feet. Changes in the posterior columns of the cord have been found. *Diabetic paraplegia* is probably due to neuritis. There are cases with loss of power in both arms and legs.

Mental Symptoms.—The patients are often morose, and there is a strong tendency to become hypochondriacal. Some patients display an extraordinary degree of irritability, restlessness and anxiety.

(f) **SPECIAL SENSES.**—Cataract is liable to occur, and rapidly in young persons. *Diabetic retinitis* closely resembles the albuminuric form and is probably due to vascular changes. Hæmorrhages are common. Sudden amaurosis, similar to that in uræmia, may occur. Paralysis of the muscles of accommodation and atrophy of the optic nerves may be present. *Lipæmia retinalis* may occur; the retinal vessels are white against a pink background. Aural symptoms may come on with great rapidity, an otitis media or inflammation of the mastoid cells. Ocular tension may be lowered in coma.

(g) **REPRODUCTIVE FUNCTIONS.**—Impotence is common and may be an early symptom. Conception is rare; if it occurs, abortion is apt to follow. A diabetic mother may bear a healthy child; there is no known instance of a diabetic mother bearing a diabetic child. The course of the disease is usually aggravated after delivery.

(h) **CIRCULATION.**—*Arterio-sclerosis* is common in elderly diabetics and the changes in the arteries of the legs increase the danger of gangrene of the feet. Hypertension is relatively common; Kramer found it in nearly 40 per cent. of his series. The association of obesity probably plays a part. There may be a possible causal influence in arterio-sclerosis of the pancreatic vessels.

Diagnosis.—There is no difficulty in determining the presence of sugar in the urine if the proper tests are applied. Alcapton may prove deceptive, and in one reported case of ochronosis (Osler) a diagnosis of diabetes was made by five of the leading physicians in Europe, one of whom was an authority on diabetes. Deception may be practised. Levulose, lactose and pentose should be kept in mind as possible causes of error. Certain drugs yield reducing substances in the urine.

To determine whether the case is one of simple alimentary glycosuria or diabetes is not always easy, as the one readily merges into the other. It is well to test the assimilation limit; 100 grams of glucose given to a fasting patient should not give glycosuria. The determination of the sugar in the blood is an important aid; a blood sugar above 0.12 per cent., taken when fasting, usually means diabetes. To preserve blood for this test add one drop of 40 per cent. formaldehyde solution to each 5 c. c. The specimen can be used within 3 days. A thorough test of the sugar tolerance is of great value in a doubtful case. The diagnosis of *renal glycosuria* depends on a persistent glycosuria independent of the amount of carbohydrate intake, a low or normal amount of sugar in the blood and the absence of the usual features of diabetes.

In a sugar tolerance test the amount of blood sugar does not rise above normal limits and hypoglycæmia within 90 minutes of ingestion of dextrose is against diabetes. Hamochromatosis should not cause difficulty. The detection of a little sugar in the urine may have the great advantage of frightening the patient into a more rational mode of life. The forms following anæsthesia, accidents, business worries, fright and that which occurs in pregnancy are, as a rule, readily controlled.

Chronic *Glycopenia* or *Hypoglycæmia*. Some individuals have a blood sugar of 0.08-0.09 per cent. with weakness, headache, gastro-intestinal disturbance and especially constipation. Sometimes a low blood sugar content comes on in the late forenoon or afternoon with sudden weakness. In the chronic cases under-activity of endocrine glands may be responsible by influencing the glycogen formation in the liver or hyperinsulinism may exist. In the acute forms the taking of dextrose or other sugar is effectual. In the chronic forms the effect of various amounts and forms of carbohydrate should be studied and internal secretion therapy given if indicated. Over-secretion of insulin has occurred in carcinoma of the islands of Langerhans; some cases have been successfully treated surgically.

Prognosis.—This has been materially improved by the discovery of insulin, but the same general rules still apply and there is the same need of intelligent care. The social condition, the intelligence of the patient and his or her capacity to obey orders, the ability to obtain a proper diet and, above all, the physician himself are important factors. The patient who will not do as he is told has a heavy handicap. The occurrence of complications and infections influences the outlook materially. Complete restoration of normal carbohydrate tolerance is very rare and usually occurs only in mild cases. The results of treatment and the carbohydrate tolerance which the patient acquires are important factors.

Treatment.—In families with a predisposition to the disease the use of starchy foods and especially of sugar should be restricted. It is important to reduce overweight especially in those over forty years of age. The personal hygiene of a diabetic patient is of the first importance. Sources of worry should be avoided, and he should lead an even, quiet life, if possible in an equable climate. The heat waste should be prevented by wearing warm clothes and avoiding cold. A warm, or, if robust, a cold, bath should be taken every day. An occasional Turkish bath is useful. Systematic, moderate exercise should be taken. When this is not feasible, massage should be given. Special attention should be given to the care of the feet to reduce the danger of gangrene.

Each patient presents an individual problem and should be studied as such. Exact records should be kept of the food intake and of the urine examinations. It is an advantage, certainly early in treatment, to examine single specimens. The endeavor is to keep the urine sugar free, the blood sugar as near normal as possible, and the patient in the best general condition. Physicians and students are often puzzled by the various methods employed, which seem to differ so markedly. It is not possible here to do more than indicate the general principles. There is abundant literature which can be consulted; Joslin's book is excellent. The majority of patients do well on any proper treatment *carefully supervised*. In the more difficult cases the physician may have to try different methods to find the one best adapted to that patient.

Education of the patient is essential; he should know the nature of his disease and its dangers, and must learn food values as thoroughly as he knows the value of coins. He should learn to weigh his food and test his urine.

DIET.—There are several methods and, in general, the one employed should be as simple as possible. Sudden changes in diet should not be made without careful consideration and if in doubt it is safer to have a patient on too low than too high a diet. Effort should be made to avoid monotony and there are many changes which can be made by careful study of food tables. The intelligence of the patient should be studied and we should be sure that he understands the instructions. If possible the patient should be in bed and in a hospital for study and instruction for a sufficient period. The severity of the disease influences the treatment. Mild cases do with simple dietary restrictions. Moderately severe and severe cases require more rigid treatment. The ratio of the ketone-forming elements to the anti-ketone forming elements should be such that acidosis will not result. In this 1 gram of carbohydrate represents 1 gram of glucose, 1 gram of protein 0.58 gram of glucose, and 1 gram of fat 0.1 gram of glucose. With care, difficulty should be rare, as higher ratios of fat to carbohydrate than 1.5 are well tolerated. One gram of glucose used in the body results in the utilization of 1.5 to 2.5 grams of fatty acid. Nitrogen balance should be maintained, for which 0.66 gram of protein per kilogram of weight is a minimum if there are sufficient total calories, but in any case the protein should not exceed 1 gram per kilogram of weight. A total of 25-30 calories per kilogram of weight is sufficient at rest.

In all methods the principle of restriction of the total diet is employed. In one, special emphasis is placed on under-nutrition, so that the patient is at a lower level of weight and metabolism than his normal, to control the glycosuria and hyperglycæmia. This spares the metabolic functions. With the under-nutrition and loss of weight, the tolerance is increased. The studies of Allen proved the value of this method. In it periods of fasting, sometimes alternating with days of very low intake in all foods, are used with a gradual increase, at first in protein. A slight return of sugar, especially in elderly and sclerotic patients, need not cause any change, but if more the diet is reduced for one or two days. Any system should not be followed too rigidly and modifications should be made as the study of the patient indicates. In general it may be said that a conservative course is usually the best, that is, it is not advisable to give large quantities of carbohydrate or fat. The use of insulin permits much greater flexibility in the diet.

The treatment by high fat diet was introduced by Newburgh and Marsh. In this the diet contains a large proportion of fat and a small proportion of protein and carbohydrate. The patient's general condition is better and under-nutrition is avoided. In an adult patient they begin with a diet of 15 to 20 grams of protein, 85 to 95 grams of fat and 10 to 12 grams of carbohydrate. For children corresponding amounts are used. After sugar disappears from the urine the diet is gradually increased until $\frac{2}{3}$ of a gram of protein and 30 to 40 calories per kilogram of weight are given, with not more than 35 grams of carbohydrate. There are various formulas used to estimate the ratio of fat to carbohydrate but as a practical matter if the urine is sugar free, it is safe to give fat in three times the amount of carbohydrate if the protein is not more than 1 gram per kilogram of weight.

The following course may be followed in cases other than severe forms. The patient should be put to bed and given a maintenance diet calculated for his weight and age. In general practice this can be calculated from the proper weight for the height and sex, on a basis of 25 to 30 calories per kilogram, or the standards of DuBois or Dreyer may be used. The amount of protein should be 0.7 to 1 gram per kilogram of weight in an adult and somewhat more in a child. The amount of carbohydrate and fat necessary to supply the total calories should be given in proportions to prevent ketosis. The ratio of 3 grams of fat to 1 gram of carbohydrate is safe. If the patient becomes sugar free on this diet, the tolerance is studied and the best diet found. The protein should not exceed 1 gram per kilogram weight. If the fatty acids in grams are not more than 1.5 times the total glucose from all sources, the diet is usually satisfactory. The fatty acid content = $0.46 \text{ protein} + 0.9 \text{ fat}$. The glucose content = $\text{carbohydrate} \mp 0.58 \text{ protein} + 0.1 \text{ fat}$. If the patient is not sugar free in six or seven days insulin should be given. We must remember that all the food eaten is not necessarily absorbed.

Saccharine may be used for sugar. It is an advantage in using vegetables which are boiled in cooking, to do the boiling in three different waters, all the water being removed after each boiling. This reduces the amount of carbohydrate, an advantage for patients who demand bulk in the diet.

Insulin.—The discovery of insulin by F. G. Banting, working with C. H. Best and J. B. Collip, in association with J. J. R. MacLeod, has revolutionized the treatment of diabetes. It is an aqueous solution of the active principle of the islands of Langerhans. One unit causes an average utilization of 1.5 to 2 grams of glucose. There are certain precautions to be taken in its use. The first is to be sure that the patient has diabetes mellitus; "renal glycosuria" should be excluded. Blood sugar estimations are of great importance in controlling its administration and should be obtained if possible. The regulation of diet should be even more careful when insulin is being given, which should be administered hypodermically half an hour before meals.

Dosage.—In ordinary conditions it is best to begin with one to five units, two or three times a day before meals, gradually increasing by one unit, either with each successive dose or one unit a day, until the required dosage is found. The daily amount required in many patients runs between 10 and 20 units a day. Two doses a day are usually best given before breakfast and supper and at lunch relatively little carbohydrate. The dietetic management should be carried on much as if insulin was not being given. The best adjustment between the amount of carbohydrate and insulin requires good judgment. The danger of *hypoglycemia* is important. Every patient should be given careful instruction as to its symptoms and treatment. The minor symptoms are restlessness and nervousness, sudden weakness, perhaps with a feeling of hunger, vasomotor disturbance shown by flushing or pallor, and vertigo. The more severe features are sweating, tremor, anxiety or excitement, psychical disturbance, low blood pressure, transient hemiplegia, convulsions and collapse. For the minor features the patient should take a lump of sugar, some candy, the juice of an orange or three ounces of milk. In more severe cases 20 grams of glucose or corn syrup can be given by mouth, or by stomach tube or by rectum if the patient can not swallow. In a very severe case 10 to 20 grams of dextrose should be given intravenously in 10 per cent.

solution. Epinephrine (5-15 m of the 1-1000 solution) should be given hypodermically. Unusual exercise, digestive disturbance, a meal delayed or omitted, or increase in carbohydrate tolerance may be responsible, as well as too large a dose of insulin. Carbohydrate should be given freely (75 to 100 grams) for two or three days after marked insulin hypoglycæmia.

Coma.—It is well to warn the patient to regard any unusual symptom, especially fever, as a possible warning of coma. He should go to bed at once and notify the physician. Fluid should be taken as freely as possible and it is well to take the juice of one orange. An enema should be given at once. Treatment should be carried out most energetically: (1) *Rest* should be absolute. (2) *Fluid* should be given as freely as possible by the mouth, by the bowel or subcutaneously. Care should be taken not to cause vomiting by too large amounts by mouth. The fluid by bowel can be given by the drop method or by injecting 300 to 500 c.c. of salt solution. It is well to give salt solution subcutaneously (750 to 1000 c.c.) at once. (3) *An enema* should be given as soon as possible so that fluid can be given by the bowel if necessary. (4) *Food*. The only form necessary is carbohydrate and not more than 50 grams in the 24 hours is required. This can be given as orange juice. If there is constant vomiting, 25 grams of glucose can be given by rectum or, if this is not possible, intravenously. (5) *Insulin*. Before this is given there should be certainty that the condition is diabetic coma. The dose of insulin should be carefully considered and no set rules can be given. The danger of over-dosage should always be kept in mind. It is usually safe to give 15 units intravenously for the first dose. The repetition of this must depend on the condition: 10 or 15 units may be given intravenously in an hour. After this the repetition and dosage must depend on the results. Subcutaneous administration is advisable, after two intravenous doses, at intervals of two to four hours. The urine should be examined frequently and the blood sugar estimated if possible. Carbohydrate should be given in amounts of half to one gram for each unit of insulin. The insulin should be given in doses of 30 to 40 units for some days. (6) *Alkalies*. There is much difference of opinion as to their value and as to the dosage if they are employed. The opinion of Joslin, who does not use them, must carry great weight. If employed the dosage should not be over 10 or 15 grams a day of sodium bicarbonate. (7) *Circulation*. This should be supported by digitalis and caffeine if necessary.

Complications.—The use of insulin is of great aid. In acute infections the danger of acidosis should be remembered. In conditions requiring surgery the patient should be carefully treated until he is in the best possible condition. Fluids should be given freely. If an emergency operation has to be done carbohydrate can be given as orange juice. With infection it is not wise to adopt too rigid a diet. As to the anæsthetic, nitrous oxide with oxygen or a local anæsthetic is best. Carbuncles should be operated on early. The patient with *gangrene* should be given insulin and a surgical opinion secured at once. In general, early operation is wise.

MEDICAL TREATMENT.—Opium and its derivatives are sometimes useful for irritable patients or bromide may be given. The bowels should be kept open and for this mineral oil, cascara, senna and phenolphthalein are most useful. Purging should be avoided. *Pruritus* is best treated by lotions of boric acid or hyposulphite of soda, or by sedative ointments.

FOODS ARRANGED APPROXIMATELY ACCORDING TO CONTENT OF CARBOHYDRATES

	5% ±	10% ±	15% ±	20% ±
VEGETABLES	Lettuce	Cauliflower	Onions	Potatoes
	Spinach	Tomatoes	Squash	Shell Beans
	Sauerkraut	Rhubarb	Turnip	Baked Beans
	String Beans	Egg Plant	Carrots	Green Corn
	Celery	Leeks	Okra	Boiled Rice
	Asparagus	Beet Greens	Mushrooms	Boiled Macaroni
	Cucumbers	Water Cress	Beets	
	Brussels Sprouts	Cabbage		
	Sorrel	Radishes		
	Endive	Pumpkin

1 gram protein contains 4 calories.
 1 " carbohydrate contains 4 calories.
 1 " fat contains 9 calories.
 1 " alcohol contains 7 calories.

1 kilogram—2.2 pounds.
 6.25 grams protein contain 1 gram nitrogen.
 A patient "at rest" requires 30 calories per kilogram body weight.

CHART XIV.—DIABETIC FOOD TABLE. (JOSLIN.)

With coexisting pulmonary tuberculosis the usual diabetic treatment can be employed.

Synthalin.—Certain guanidine derivatives (synthalin and neo-synthalin) though still in the experimental stage and contraindicated in the presence of hepatic and renal disease, and severe ketosis, are effective in reducing glycosuria and blood sugar. Though most effective in mild diabetes (given orally in doses of 10 mg. three times daily, before meals, omitting every third day, owing to the cumulative effect) the tendency to morning hyperglycæmia and the necessity of a fourth daily dose of insulin in severe diabetics are frequently avoided by giving 10 mg. before the evening meal. Loss of weight, anorexia, nausea, diarrhœa and distaste for fat are indications for discontinuance or reduction of the dosage.

III. DIABETES INSIPIDUS

Definition.—A chronic affection characterized by the passage of large quantities of normal urine of low specific gravity. It is to be distinguished from diuresis or polyuria, which is frequent in hysteria and some forms of nephritis. There may be polyuria with abdominal tumors and aneurism, tuberculous peritonitis and carcinoma. Willis in 1674 first recognized the distinction between a saccharine and non-saccharine form of diabetes.

Etiology.—The disease is most common in young persons and 85 per cent. of the patients are under 20 years of age. Males are more frequently attacked than females. The affection may be congenital. A hereditary tendency has been noted in many instances. Weil found among 91 members in four generations that 23 had persistent polyuria without any deterioration in health.

There are two main views as to the cause. In one it is regarded as disturbance of the hypothalamus with failure to regulate the output of water and chloride by the kidney. The other view stresses disturbance of the function of the pituitary gland probably due to inhibition or arrest of secretion of an antidiuretic principle. A number of conditions seem to stand in an etiological relationship—injury to the base of the skull, tumors, lesions of the pituitary gland and medulla, and syphilis (basal and meningitic, a gumma in the fourth ventricle, endarteritis with changes). Hemianopsia is found in a number of the cases. In general, irritation or injury in the region of the fourth ventricle, of the tuber cinereum or hypothalamus (possibly from pressure on the pituitary gland), and of the region bounded in front by the optic chiasm and posteriorly by the peduncle prominence may be responsible. It is possible that the mechanism is not always the same. In some cases the capacity of the kidney to eliminate salt and urine is diminished. Cushing suggested that disturbance of the pituitary function through its autonomic nervous connections may explain the polyuria in functional nervous disturbance.

Morbid Anatomy.—There are no constant anatomical lesions. The kidneys have been found enlarged and congested. The bladder has been found hypertrophied. Dilatation of the ureters and of the pelves of the kidneys has been present. Death has not infrequently resulted from chronic pulmonary disease. Very varied lesions have been met with in the nervous system.

Symptoms.—The disease may come on rapidly, as after a fright or an injury; more commonly it is gradual. A copious secretion of urine, with

increased thirst, is the prominent feature. The amount of urine in the twenty-four hours may range from 20 to 40 pints, or even more. Trousseau speaks of a patient who consumed 50 pints of fluid and passed about 56 pints of urine in the twenty-four hours. In some cases the amount passed is greater than that ingested in liquids and solids. The specific gravity is low, 1.001 to 1.005; the color is extremely pale and watery. The total solid constituents may not be reduced. The amount of urea has sometimes been found in excess. Abnormal ingredients are rare. Muscle-sugar, inosite, has been found. Albumin is rare. Traces of sugar have been met with.

Naturally, with the passage of such enormous quantities of urine, there is a proportionate thirst, and a great inconvenience is the necessity for frequent micturition and frequent drinking. The appetite is usually good, rarely excessive as in diabetes mellitus; but Trousseau tells of the terror inspired by one of his patients in the keepers of eating-houses where bread was allowed without extra charge to the extent of each customer's wishes, and says that the man was paid to stay away. The patients may be well nourished and healthy-looking and the disease in many instances does not interfere with the general health. The amount of saliva is small and the mouth usually dry. The tolerance for alcohol is remarkable.

Course.—This depends largely upon the nature of the primary trouble. Sometimes, with organic disease, the general health is much impaired; the patient becomes thin, and rapidly loses strength. The affection has persisted for fifty years. Spontaneous cure may take place.

Diagnosis.—A low specific gravity and the absence of sugar in the urine distinguish the disease from diabetes mellitus. Hysterical polyuria may simulate it very closely. The amount of urine may be enormous, and only the development of other hysterical manifestations may enable the diagnosis to be made. This condition is, however, always transitory. In certain cases of chronic nephritis a very large amount of urine of low specific gravity may be passed, but the presence of albumin and casts, high blood pressure, stiff vessels, and hypertrophied left ventricle make the diagnosis easy. Careful search should be made for syphilis and an X-ray study done of the sella turcica.

Treatment.—No attempt should be made to reduce the amount of liquid. In some cases gradual reduction of the protein and salt intake is useful. This should be done gradually. Administration of the extract of the posterior lobe of the pituitary (1 c.c. a day) has been useful. As a rule this has to be given by injection, but in some cases the application to the nasal mucous membrane has been successful. Some patients improve under large doses of thyroid extract. Lumbar puncture has been followed by marked improvement and should be tried. Theocin is sometimes useful in doses of 5 grains (0.3 gm.) three times a day. Antisyphilitic treatment should be given in patients with a suspicious history or a positive Wassermann reaction.

IV. OBESITY

Definition.—A disorder of metabolism characterized by excessive deposit of fat in the body.

Etiology.—Corpulence, an overgrowth of the bodily fat, an "oil dropsy,"

as Byron termed it, is a common condition which may be a source of great bodily and mental distress. There are a number of factors to consider:

(1) Hereditv. This is important and figures in a considerable number of cases. We perhaps inherit a habit of metabolism. Obesity may occur on a food intake below the usual normal. The basal metabolism may be normal. The specific dynamic action of protein may be less marked than normal. Sometimes the eating habits of the family are responsible rather than heredity.

(2) Simple obesity is due to disproportion between the food intake and the bodily activity. In these cases the basal metabolism is normal. The increased weight, especially if there is anæmia, renders exercise difficult and a vicious circle is established. Too much food and too little exercise are the causes in this group. Alcohol may play an important part, especially the malt liquors, both in the extra intake and perhaps through interference with metabolism. The lack of exercise results in less oxygen supply and so decreased oxidation.

(3) Metabolism. There is a low basal metabolism in some patients, which may be a peculiarity or due to underactivity of the thyroid gland. Some patients show a marked retention of water. Decreased oxidation results from lack of exercise and anæmia. The latter may be important as the oxygen-carrying capacity is reduced.

(4) Internal Secretions. These play an important part. The influence of the gonads is seen in the increased fat in eunuchs, castrated animals, in some women after the menopause and during pregnancy, and in girls at puberty. The influence of the thyroid gland is often evident, through its effect on metabolism. In the obesity of hypothyroidism the patients have a round fat face ("moon face") and a fat neck. Particular interest belongs to the pituitary gland, especially underactivity of the posterior lobe. The face and neck are not fat, the deposit of fat being particularly about the lower part of the trunk, around the pelvis and on the upper parts of the thighs. Tumors of the gland or in its neighborhood may be associated with adiposity and sexual infantilism (Fröhlich's syndrome). With the removal of the posterior lobe there is marked increase in weight (Cushing).

(5) Juvenile obesity is due in a large proportion of cases to insufficiency of the posterior lobe of the pituitary gland.

Pathology.—The fat is deposited in the subcutaneous tissues, mesentery, omentum and about the organs, especially the heart and kidneys. The pericardial fat may be greatly increased and penetrate between the muscle fibres. The liver may contain large amounts of fat.

Symptoms.—Inconvenience caused by the bulk, and loss of good looks in women, are the features for which we are usually consulted. While fat is no sign of health, the great bulk may be consistent with remarkable vigor and activity. Shortness of breath, embarrassed cardiac action and difficulty in walking are the most common complaints. In children obesity is often associated with careless habits in eating and lack of proper control on the part of parents. The condition is increasing, particularly in the United States, where one sees an extraordinary number of very stout children. A remarkable phenomenon associated with excessive fat is an uncontrollable tendency to sleep—like the fat boy in Pickwick. It is probable that this narcolepsy is a manifestation of disturbed pituitary function.

Prognosis.—This depends on the recognition of the cause and the pos-

sibility of influencing it. Naturally the character of the patient counts for much as co-operation is essential. In hereditary cases the outlook is always doubtful. Obesity is always a danger, especially if the subject has an acute infectious disease, such as pneumonia. It plays an important part in the etiology of diabetes mellitus and vascular diseases, especially hypertension.

Treatment.—The famous George Cheyne, a man of enormous bulk, reduced himself by dieting from 448 pounds to proper dimensions. One of his aphorisms says: “Every wise man after Fifty ought to begin and lessen at least the quantity of his Aliment, and if he would continue free from great and dangerous Distempers and preserve his Senses and Faculties clear to the last, he ought every seven years to go on abating gradually and sensibly, and at last descend out of life as he ascended into it, even into a Child’s Diet.” Put in other words, it reads—We eat too much after fifty years of age.

A study of the basal metabolism should be made if possible. Careful records should be kept of the food and liquid intake, amount of urine and the weight. It is best to have the patient at rest in a hospital for a time at the onset of treatment in severe cases. No attempt should be made at rapid reduction; two pounds a week is usually sufficient.

Diet.—In mild cases restriction of the carbohydrates and fats may be enough. In severe cases it is well to reduce the calories fairly rapidly. In any case a daily intake of about 1500 calories is usually satisfactory. The reduction should be largely in the carbohydrates and fats; the amount of protein should be kept about 90 grams per day. Sugar and candy should be forbidden; saccharine may be used. The non-carbohydrate flours used in diabetes may be useful. In some patients the total calories may be reduced to 1200; in others larger amounts than 1500 may be required. It is well to restrict the fluid intake to about 1200 c.c. per day. In children proportionate amounts should be given. Some patients do well on two meals a day; others are better with four small meals. (a) Fast days. One day a week when only tea or coffee and a little bouillon are taken is an advantage. At first the patient should stay in bed for this and later he may be about. (b) Milk days on which only milk is taken, up to a quart. (c) Green vegetable days on which small amounts of these are taken, perhaps with some bouillon. In the method used by B. L. Gordon, the usual intake of starch is reduced one-third and one dextrose lozenge (2 gm.) is taken every half hour from 9–11.30 A. M., 2.30–5 and 8–9.30 P. M. No change is made in the intake of fat or protein.

Exercise.—This must be used with judgment. In severe cases at first it should be by massage or by one of the methods for “local exercise” by special apparatus. Exercises carried on with the patient lying are useful. The amount of walking can be gradually increased; if up grade this should be taken into account. Gymnasium work should be carefully controlled. It is well to examine the patient occasionally after exercise to study the result.

Bathing.—Cold baths with vigorous rubbing or exercises afterwards are an advantage. Very hot baths or Turkish baths may be dangerous.

Drugs.—Thyroid extract is most effectual in patients with a low basal metabolism. It should not be given routinely. It is wise to begin with one grain (Thyroideum siccum, U. S. P.) daily and gradually increase until the best dosage for the patient is found. It is well to omit it for a few days occasionally and it should be stopped at once if any signs of disturbance appear.

In some cases the addition of a small amount of pituitary gland extract is helpful. In fat children in whom hypopituitarism seems present, a combination of pituitary and thyroid may be tried, or either alone. The best dosage or combination has to be found for each patient. Thyroid gland administration is useful in some cases of obesity about the menopause. Cathartics are given as required, salines usually being best. Drastic purgation is not wise. Anæmia should be treated by iron and arsenic.

V. THE LIPOMATOSES

Various forms of localized deposits of fat may be considered here, and we follow the division in Lyon's thorough study of these conditions.

I. Adiposis Dolorosa (*Dercum's Disease*).—In the words of the original description this is a disorder characterized by irregular symmetrical deposits of fatty masses in various portions of the body, preceded or attended by pain, and associated sometimes with asthenia and psychical changes.

The lipomatous masses are diffuse and symmetrical, involving the abdomen, chest, arms or legs; or localized on the limbs or trunk. The hands, face and feet are usually spared. The pain is sometimes spontaneous and is easily excited by pressure. Asthenia, not always present, may be a marked feature. The patients are often irritable and there are cases with mental changes. Sometimes the skin over the areas of infiltration is markedly hyperæsthetic. The affection is more common in females. Autopsies have not thrown clear light on the pathology. Quite probably it is an internal secretion disturbance.

II. Nodular Circumscribed Lipomatosis.—The cases are common. The lipomata are distributed in various localities and vary in size from small encapsulated nodules to large circumscribed tumors, solitary or multiple, sometimes symmetrically placed. They may be painful, and Lyon notes that the accessory features of asthenia and psychical changes may be present.

III. Diffuse Symmetrical Lipomatosis of the Neck.—This remarkable affection, also called adeno-lipomatosis, is characterized by symmetrical fatty infiltrations, either simple or lobulated, of the subcutaneous tissues, forming a huge collar about the neck. It may occur in this part alone or other limited lipomata are found elsewhere. Males are much more frequently attacked than females. The tumors interfere but little with health, but as they increase the condition becomes very disfiguring. There are sometimes constitutional symptoms. The name "adeno-lipomatosis" has been given because scattered throughout the diffuse fatty masses there are small firm nodules of lymphatic tissue—sometimes hæmo-lymph glands.

IV. Cerebral Adiposity (*Dystrophia Adiposo-genitalis, Fröhlich*).—A condition of obesity may occur with disturbance of the hypophysis, or adjacent parts, associated with a hypoplasia of the genital organs and infantilism. The condition will be discussed in the section on internal secretions, as it appears to be associated with perversion of the function of the pituitary gland.

V. Pseudo-Lipoma.—Sydenham made the keen observation that in hysterical patients there were sometimes swellings, which neither yielded to the impress of the finger nor left a mark. Charcot described the condition as "hysterical œdema," of which there is both a blue and white variety.

Many of these subcutaneous infiltrations, just as in the soft, supraclavicular pad, so common in stout women, are due to fat, and French writers describe all grades of transition from a pseudo-œdema to a true lipoma.

Treatment.—This is not satisfactory. A trial of thyroid extract in small doses is advisable, but it is well to suspend its use for a week in every month. Extracts of other glands may also be tried. In patients with signs of tumor of the hypophysis surgical measures should be considered. In adiposis dolorosa large doses of thyroid gland may be advisable and pituitary extract may be tried. Sedatives are generally advisable.

VI. HÆMOCHROMATOSIS

Definition.—A disorder of metabolism characterized by a deposition of an iron-containing pigment in the glandular organs, and by an increase in the normal pigmentation with which is associated a progressive sclerosis of various organs, and, in a large proportion of the cases, diabetes. The disease was first described by von Recklinghausen.

Etiology.—Of the cases on record the great majority had diabetes. It very rarely occurs in females. In the majority of the patients, middle-aged men, there seemed to be no marked predisposing causes, though Blumer maintains that alcohol plays an important part. The ingestion of copper has been suggested and large amounts may be found in the liver (140 mg. per kilogram in one of my cases), but this is probably due to deficient excretion. We all absorb copper every day and the influence is not proved. Primary carcinoma of the liver may occur with it (in 12 of 128 cases reported to 1927). There are two main theories, one that it is due to excessive hemolysis and the other that it is a primary disturbance in iron metabolism.

Pathology.—On autopsy the ochre or bronze color of the organs is the striking feature. The liver is large and sclerotic; the spleen also enlarged, and the pancreas either small and atrophic or fatty and fibroid. The lymph nodes are also pigmented. The pigment is hæmosiderin or iron-reacting. It is chiefly in the cells of the glands, in the muscle cells of the heart, and in the lymph nodes. The amount in the various organs is enormous, a hundred times the normal in the liver, for example. The hæmofuscin, the non-iron-reacting pigment, has a yellow tint, and is found chiefly in the connective tissue cells. The blood shows no special changes.

Rous and Oliver produced an identical condition in rabbits by repeated transfusions of blood, so that large amounts were being constantly destroyed.

Clinical Features.—There are two groups of cases, the larger one in which diabetes is present, and the smaller in which there is no sugar in the urine. The former group is spoken of by the French as *diabète bronzé*, which has the features of a severe diabetes with weakness, progressive pigmentation of the skin, and an enlarged liver. The pigmentation of the skin which is the feature that attracts attention varies in color from a dark brown to a leaden or bluish black. Dr. Maude Abbott's case was known as *Blue Mary*. The liver shows cirrhosis with a smooth and uniform enlargement. The spleen may be enlarged secondarily. It was very large in two of our cases. The diabetes is usually severe, and runs a rapid course.

There is no special treatment beyond measures for the general health; in the patient with diabetes the usual treatment should be carried out, but insulin therapy may cause severe reactions with rapid changes in the blood sugar. There is a strong tendency to acidosis.

VII. OCHRONOSIS

Definition.—A rare disorder of metabolism associated with blackening of the cartilages and fibrous tissues and pigmentation of the skin, and the presence of dark urine due to alcapton or to derivatives of carboic acid.

Etiology.—There are two groups of cases:

(a) There is a congenital life-long chemical malformation in which there is a failure to burn homogentisic acid (alcapton body) formed from tyrosine and phenylalanine with the result that some is excreted in the urine (alcaptonuria) and some is stored in the tissues. The anomaly may be present in three generations.

(b) In the other group the dark urine and the blackening of the tissues are due to the prolonged use of carboic acid, usually the application of strong solutions externally. There may be a third group with melanuria. In 1929, Goldberg found 51 cases, of which 12 were carbol-ochronosis.

Symptoms.—When well developed, ochronosis presents a striking picture. The discoloration of the fibrous tissues is best seen about the knuckles, and in thin persons the tendons of the hands and feet show a bluish-gray appearance. The cartilage of the ear has a bluish tint, and there may be symmetrical black patches on the sclerotics. Widespread pigmentation of the skin has been observed. In one patient there was a coal-black discoloration of the skin over the nose and cheeks, and the same was beginning in the hands. This may occur also in the carboluria group. Several of the reported cases had arthritis, and two brothers in the Maryland family had a curious anterior inclination of the trunk with a peculiar waddling gait. There are few symptoms directly due to the chemical malformation. There is usually marked arterio-sclerosis. Post mortem, the cartilages, ligaments and fibrous structures are everywhere of a brown-black color.

VIII. ACIDOSIS

Definition.—Acidosis may be defined as a decrease in the amount of fixed bases in the blood and other tissues of the body or in other words a relative increase in the acid ions. This involves a decrease in the alkali reserve of the body and hence a disturbance of the acid-base equilibrium. This might be described better as a decrease in the alkalinity; an actual acid condition is not present. The free carbon dioxide in the body converts the bases not bound by other acids to bicarbonate and hence the bicarbonate represents the excess of base remaining after non-volatile acids have been neutralized. Hence acidosis involves a depletion of the bicarbonate in the blood which has been termed the "first line of defence" against acidosis. A definite acid-base equilibrium is essential to life and any marked departure from it results in

serious difficulty. This equilibrium is kept at a very constant level and any increase of acid or alkali is automatically guarded against. Under ordinary conditions of diet there is production of acid radicals. These are disposed of by oxidation, elimination, excretion and neutralization.

The means by which the normal ratio is maintained are as follows: (1) Elimination of carbon dioxide by the lungs, in which sodium bicarbonate plays a large part as a carrier; (2) elimination of acid by the kidneys; (3) neutralization of acid by ammonia, and (4) intake of fixed bases with the food. It is evident that oxidation plays a large part in the process. In disturbance of the usual acid-base relations the body endeavors to protect itself by an increase in the normal processes. One important means is increased neutralization of acid by ammonia. The ratio of this to the total N of the urine, which normally is 2 to 5 per cent., may rise to 25 or even 40 per cent. By an increased respiration rate the effort is made to excrete more carbon dioxide by the lungs. The kidneys may excrete more acid than in normal conditions. The reserve of alkali is used so far as it is available. These means may not be sufficient and a decrease in the amount of sodium bicarbonate will result in less CO₂ being carried from the tissues and hence an accumulation of it there. From this dyspnœa and air hunger result. So long as the reduction in the alkali reserve is not marked the condition is not serious, but if this does result many changes follow, disturbance in oxidation, disturbed renal function, altered N metabolism, dyspnœa, etc.

The mechanism of this decreased alkaline reserve is various. In diabetes mellitus there is excessive formation of ketone bodies. In certain of the diarrhœal diseases it may be that alkali is excreted by the bowel; this probably occurs in cholera. In conditions in which there is loss of fluids there may not be sufficient fluid available. The kidneys may not excrete the normal amount of acid phosphates or may be unable to increase the excretion to meet an emergency.

Occurrence.—Acidosis may occur in many diseases, in some of which it is of slight significance only, in others of extreme gravity. The more important are as follows:

(1) **STARVATION.**—This applies particularly to the absence of carbohydrates from the diet. It is probably a factor in the production of acidosis in acute infections in which there is difficulty in giving sufficient food, and may contribute to the acidosis after anæsthesia, especially in cases in which little or no food has been taken for some time beforehand.

(2) **ANÆSTHESIA.**—Slight grades of acidosis are common and in the majority unimportant, but in a critical case the incidence of acidosis may be enough to determine a fatal outcome. Hence the wisdom of taking measures to prevent it so far as possible.

(3) **PREGNANCY.**—Here the acidosis is rarely of serious moment.

(4) **IN CHILDREN.**—In certain of the diarrhœal diseases of children, acidosis may be marked and be sufficient to determine a fatal result. The cyclic vomiting of children is often associated with acidosis. An acid intoxication may be due to a disturbance in the metabolism of the fats and proteins. The condition may come on in a perfectly healthy child, with gastro-intestinal symptoms, vomiting, diarrhœa and slight fever. On the second or third day dyspnœa appears with abdominal distention, the child begins to get drowsy,

and on the fourth or fifth day or even earlier there is coma. The urine usually contains acetone and diacetic acid.

(5) INFECTIOUS DISEASES.—Rheumatic fever, pneumonia, Asiatic cholera and typhoid fever are examples.

(6) DIABETES MELLITUS.—In this ketosis is a serious factor.

(7) RENAL AND CARBIO-RENAL DISEASE.—In this group the decrease in the ability of the kidney to excrete acids is an important factor.

Diagnosis.—(1) INCREASE IN THE RESPIRATION RATE.—In all cases of hyperpnœa for which no other cause is found, the possibility of acidosis should be considered. If the ketone bodies are responsible there is usually a fruity odor to the breath.

(2) THE CO₂ COMBINING POWER OF THE PLASMA (method of Van Slyke). The normal is usually 55 to 70 volumes per cent. Figures between 40 and 55 indicate mild acidosis. Symptoms, such as headache, malaise and hyperpnœa, usually appear when below 40, and drowsiness appears below 30 with coma at about 20.

(3) BLOOD.—(a) Lowering of the CO₂ content. (b) Decreased alkalinity. (c) Determination of the oxygen-containing power of the hæmoglobin.

(4) URINE.—(a) Increase in the ammonia. (b) Excess of acid or the presence of abnormal acids. (c) Change in the fixed bases.

(5) TOLERANCE.—Tolerance to alkalis, especially bicarbonate, measured by the amount of sodium bicarbonate required to render the urine alkaline.

Prognosis.—As acidosis is not a disease in itself, it is difficult to speak of prognosis, but the outcome of the disease which it complicates may depend on the acidosis, as for example in the diarrhœal diseases of children. In diabetes mellitus, ketosis is often the terminal event.

Treatment.—Prevention should be used whenever possible. In diabetes mellitus this is essential and should always be considered in the treatment. In general the useful measures in acidosis are: (1) The giving of water freely. (2) The administration of carbohydrate. This may be by mouth or by bowel as by the use of a 2 to 5 per cent. solution of glucose. (3) The giving of moderate amounts of sodium bicarbonate by mouth, bowel or intravenously until the urine is alkaline. This is important in the early stages, as for instance in children. In some cases the giving of sodium, calcium, potassium and magnesium salts may be of advantage. With established acidosis the treatment must depend on the underlying condition. In general the giving of sodium bicarbonate intravenously (2.5 per cent. solution) even up to 100 grams is advisable in severe cases. In milder ones the administration may be by mouth or by rectum. If possible large amounts of water should be given.

IX. ALKALOSIS

The term *alkalosis* designates a condition of increased alkali reserve; *alkalæmia* designates a decrease in the H ion concentration of the blood. The means by which the acid-base relation is kept constant have been given under acidosis. The blood is a complex fluid in which the salts, with protein and hæmoglobin, act as "buffers" and keep the reaction constant. In this regulation the sodium bicarbonate, carbon dioxide and the respiratory centre are

Best treatment if kidney
funct. is to give norm.
saline. If kidney not
funct. use 2% saline

important. Alkalosis may arise from various causes. Increased respiration, which may be voluntary, with increased respiration rate, or due to high altitudes, results in greater excretion of carbon dioxide and the alkali reserve increases. This may result in a low alkaline content of the blood, the alkali being withdrawn into the tissues. Clinical alkalosis is either alkali excess or carbon dioxide deficit. In either case the results are much the same; the urine becomes alkaline. The alveolar carbon dioxide is increased in alkali excess, decreased in carbon dioxide deficit.

A frequent cause of alkalosis is the excessive administration of alkali, usually sodium bicarbonate, as in the treatment of peptic ulcer; acetate or citrate. It may result from loss of hydrochloric acid by vomiting. The removal of the parathyroid glands produces it. The symptoms are headache, restlessness, numbness and tingling, tremor of the eyelids, anorexia, nausea, vomiting and excessive dryness of the mouth. Tetany and convulsions may follow. The facial muscles may be tense and show tremor; Chvostek's sign may be present. General oedema may be a striking feature. The blood urea may be greatly increased. Death has resulted. In *treatment*, the cause should be considered. If due to excessive giving of alkalies these should be stopped and dilute hydrochloric acid given by mouth; also if there has been marked hydrochloric acid loss. If this is not possible, ammonium chloride (250 c. c. of a 0.8 per cent. solution) should be given intravenously and very gradually. If due to excessive breathing, efforts should be made to reduce this by breathing through a tube, rebreathing into a gas bag or by giving an oxygen-carbon dioxide mixture.

SECTION VI

DISEASES OF THE DIGESTIVE SYSTEM

A. DISEASES OF THE MOUTH

Acute Stomatitis.—Simple or erythematous stomatitis, the commonest form, results from the action of irritants of various sorts. Frequent at all ages, in children it is usually associated with dentition and with gastro-intestinal disturbance, particularly in ill-nourished, unhealthy subjects; in adults it may follow the abuse of tobacco, or the use of too hot or too highly seasoned food; it is a concomitant of indigestion, or of the specific fevers.

The affection may be limited to the gums and lips or may extend over the whole surface of the mouth and include the tongue. There are at first superficial redness and dryness of the membrane, followed by increased secretion and swelling of the tongue, which is furred and indented by the teeth. There is rarely any constitutional disturbance, but in children there may be slight fever. The condition causes discomfort, sometimes actual distress and pain, particularly in mastication.

In infants the mouth should be carefully sponged after each feeding. A mouth-wash of glycerin and borax may be used, and in severe cases a one per cent. solution of nitrate of silver may be applied.

Aphthous Stomatitis.—This form, also known as *follicular* or *vesicular* stomatitis, is characterized by the presence of small, slightly raised spots, from 2 to 4 mm. in diameter, surrounded by reddened areolæ. The spots appear first as vesicles, which rupture, leaving small ulcers with grayish bases and bright-red margins. They are seen most frequently on the inner surfaces of the lips, the edges of the tongue, and the cheeks. They are seldom present on the mucous membrane of the pharynx. This form is met with most often in children under three years, either as an independent affection or in association with a febrile disease or an attack of indigestion. The vesicles come out with great rapidity and the ulcers may be fully formed within twenty-four hours. The child complains of soreness of the mouth and takes food with reluctance. The buccal secretions are increased and the breath is heavy, but not foul. The constitutional symptoms are usually those of the disease with which the aphthæ are associated. The disease must not be confounded with thrush. No special parasite has been found in connection with it. It is not serious and heals rapidly with the improvement of the constitutional state. In severe cases it may extend to the pillars of the fauces and to the pharynx, and produce irritating ulcers which are difficult to heal.

Each ulcer should be touched with nitrate of silver and the mouth should be thoroughly cleansed after taking food. A wash of chlorate of potassium, or of borax and glycerin, may be used. The constitutional symptoms should receive careful attention.

A curious affection occurs in southern Italy sometimes in epidemic form, characterized by a pearly-colored membrane with induration, immediately beneath the tongue on the frænum (Riga's disease). There may be much induration and ultimately ulceration. It occurs in both healthy and cachetic children, usually about the time of the eruption of the first teeth.

Ulcerative Stomatitis.—This form, also known as *fetid stomatitis*, or *putrid sore mouth*, occurs particularly in children after the first dentition. It may prevail as a widespread epidemic in institutions. Insufficient and unwholesome food, improper ventilation, and prolonged damp cold weather seem to be predisposing causes. Lack of cleanliness of the mouth, the presence of carious teeth, and the collection of tartar favor the occurrence of the disease. The affection spreads like a specific disease and in some cases the same organisms as in Vincent's angina have been found.

The process begins at the margin of the gums, which become swollen and red and bleed readily. Ulcers form, the bases of which are covered with a grayish-white, firmly adherent membrane. In severe cases the teeth may be loosened and necrosis of the alveolar process occur. The ulcers extend along the gum-line of the upper and lower jaws; the tongue, lips and mucosa of the cheeks are usually swollen, but rarely ulcerated. There is salivation, the breath is foul, and mastication is painful. The submaxillary lymph-glands are enlarged. An exanthem may appear and be mistaken for measles. The constitutional symptoms are often severe, and in debilitated children death sometimes occurs.

In the *treatment* chlorate of potassium has been found to be almost specific. It should be given in doses of 3 grains (0.2 gm.), three times a day, to a child, and to an adult double that amount. Locally it may be used as a mouth-wash, or the powdered salt may be applied to the ulcerated surfaces. When there is much fetor, a solution of potassium permanganate may be used as a wash, and silver nitrate applied to the ulcers. Neo-arsphenamine intravenously has proved useful in some cases.

A *variety* of ulcerative sore mouth, which differs entirely from this form, is common in nursing women, and is usually seen on the mucous membrane of the lips and cheeks. The ulcers arise from the mucous follicles, and are from 3 to 5 mm. in diameter. They may cause little or no inconvenience; but in some instances they are very painful and interfere seriously with the taking of food and its mastication. As a rule they heal readily after the application of nitrate of silver, and the condition is an indication for tonics, fresh air, and a better diet.

Recurring outbreaks of an *herpetic*, even *pemphigoid*, stomatitis are seen in neurotic individuals (*stomatitis neurotica chronica*, Jacobi). It may precede or accompany the fatal form of *pemphigus vegetans*. Parrot describes the occasional appearance in new-born, debilitated children of small ulcers symmetrically placed on the hard palate on either side of the middle line. They rarely heal, but tend to increase in size and may involve the bone. Bednar's aphthæ consist of small patches and ulcers on the hard palate, caused as a rule in young infants by the artificial nipple or the nurse's finger.

Parasitic Stomatitis (*Thrush*; *Soor*; *Muguet*).—This affection, most common in children, is dependent upon a fungus, *Oidium albicans*. It belongs to the order of yeast fungi and consists of branching filaments, from

the ends of which ovoid torula cells develop. The parasite grows in the upper layers of the mucosa, and the filaments form a dense felt-work among the epithelial cells. The disease apparently does not arise in a normal mucosa. Improper diet, uncleanness of the mouth, fermentation of remnants of food, or the occurrence, from any cause, of catarrhal stomatitis predispose to the growth. In institutions it is frequently transmitted by unclean feeding-bottles, spoons, etc. Robust, well-nourished children are sometimes affected, but it usually occurs in enfeebled, emaciated infants with digestive or intestinal troubles, in whom the disease may persist for months. It is not confined to children, but is met with in adults in the final stages of fever, in chronic tuberculosis, diabetes, and in cachectic states. The disease begins on the tongue and is seen in the form of slightly raised, pearly-white spots, which increase in size and gradually coalesce. The membrane can be readily scraped off, leaving an intact mucosa, or, if the process extends deeply, a bleeding, slightly ulcerated surface. The process spreads to the cheeks, lips, and hard palate, and may involve the tonsils and pharynx. In very severe cases the entire buccal mucosa is covered by the grayish-white membrane. It may even extend into the œsophagus and to the stomach and cæcum. It is occasionally met with on the vocal cords.

The affection is readily recognized, and must not be confounded with aphthous stomatitis, in which the ulcers, preceded by the formation of vesicles, are distinctive. In thrush the microscopic examination shows the presence of the characteristic fungus in the membrane. In this condition the mouth is usually dry, in striking contrast to the salivation with aphthæ.

Treatment.—Thrush is more readily prevented than removed. The child's mouth should be kept scrupulously clean, and, if artificially fed, the bottles should be thoroughly sterilized. Lime-water or a 2 per cent. solution of sodium bicarbonate may be employed. When the patches are present the alkaline mouth-washes may be continued after each feeding. A spray of borax or of sulphite of soda (a dram to the ounce) or the black wash with glycerine may be employed. The permanganate of potassium is also useful. The constitutional treatment is of equal importance, and it will often be found that the thrush persists, in spite of all local measures, until the general health of the infant is improved by change of air, the relief of diarrhœa, or, in obstinate cases, the substitution of a natural for artificial diet.

Gangrenous Stomatitis (*Cancrum Oris*; *Noma*).—An affection characterized by a rapidly progressing gangrene, starting on the gums or cheeks, and leading to extensive sloughing and destruction. No specific organism has been found. This terrible, but fortunately rare, disease is seen only in children under very insanitary conditions or during convalescence from the acute fevers, especially measles, more rarely scarlet and typhoid fever. It is more common in girls than in boys. It is met with between the ages of two and five years. The mucous membrane is first affected, usually of the gums or of one cheek. The process begins insidiously, and when first seen there is a sloughing ulcer of the mucous membrane, which spreads rapidly and leads to brawny induration of the skin and adjacent parts. The sloughing extends and in severe cases the cheek is perforated. The disease may spread to the tongue and chin or invade the bones of the jaws and even the eyelids and ears. In mild cases an ulcer forms on the inner surface of the cheek, which

heals or may perforate and leave a fistulous opening. The constitutional disturbance is great, the pulse rapid, the prostration extreme, and death usually takes place within a week or ten days. The temperature may reach 103° or 104° F. Diarrhœa is usually present, and aspiration pneumonia is a common complication. Destruction of the sore by the cautery is the most effectual treatment. Antiseptic applications should be used to lessen the fetor. The child should be carefully nourished and stimulation used freely.

Mercurial Stomatitis (*Ptyalism*).—It occurs in persons with a special susceptibility, rarely as a result of the excessive use of the drug, and also in those whose occupation necessitates the handling of mercury. It may follow the administration of repeated small doses of calomel or gray powder. The patient complains first of a metallic taste in the mouth, the gums become swollen, red, and sore, mastication is difficult, the salivary glands become enlarged and painful, and there is a great increase in their secretion. The tongue is swollen, the breath is foul, and there may be ulceration of the mucosa, and, in rare instances, necrosis of the jaw. The condition is rarely serious, and recovery usually takes place in a couple of weeks. Instances in which the teeth become loosened or in which the inflammation extends to the pharynx and Eustachian tubes are rare.

The administration of mercury should be suspended so soon as the gums are "touched." Mild cases subside within a few days and require only a simple mouth-wash. In severer cases chlorate of potassium may be given internally, and used to rinse the mouth. The bowels should be freely opened; the patient should take a hot bath every evening and drink plentifully of alkaline mineral waters. Atropine is serviceable, and may be given in doses of 1/100 of a grain (0.00065 gm.). When the salivation is severe and protracted the patient becomes much debilitated and anæmic, so that a supporting treatment is indicated. The diet is necessarily liquid, for the patient finds great difficulty in taking food. If the pain is severe Dover's powder may be given at night.

Here may be appropriately mentioned the influence of stomatitis, particularly the mercurial form, upon the developing teeth of children. The condition known as *erosion*, in which the teeth are honeycombed or pitted owing to defective formation of enamel, is indicative, as a rule, of infantile stomatitis or of severe illness before the second dentition. Such teeth must be distinguished carefully from those of congenital syphilis, which may coexist, but the two conditions are distinct. The honey-combing is frequently seen on the incisors; but, according to Jonathan Hutchinson, the test teeth of infantile stomatitis are the first permanent molars, then the incisors, "which are almost constantly pitted, eroded, and of bad color, often showing the transverse furrow which crosses all the teeth at the same level."

Geographical Tongue (*Eczema of the Tongue*).—A remarkable desquamation of the superficial epithelium of the tongue in circinate patches, which spread while the central portions heal. Fusion of patches leads to areas with sinuous outlines. When extensive the tongue may be covered with these areas, like a geographical map. The affection causes a good deal of itching and heat, and it may be a source of much mental worry to the patients, who often dread that it may be a commencing cancer.

The *etiology* is unknown. It occurs in infants and children, and it is

not very infrequent in adults. Transient attacks may accompany indigestion. It is very liable to relapse and in adults it may prove very obstinate. Solutions of nitrate of silver give the most satisfactory results.

There is a superficial *glossitis*, limited usually to the border and point of the tongue, which presents irregular reddish spots, as if the epithelium was removed; the papillæ are reddened and swollen. It is sometimes known as Möller's glossitis. Local treatment with nitrate of silver gives relief.

Leukoplakia buccalis.—Samuel Plumbe described the condition as *ichthyosis lingualis*. It has also been called *buccal psoriasis* and *leuko-keratosis mucosæ oris*. The following forms occur: (a) Small white spots upon the tongue, slightly raised, even papillomatous—lingual corns. (b) Diffuse thickening of the epithelial coating of the tongue, either a thin, bluish-white color or opaque white, depending upon the thickness. It is patchy and more often upon the dorsum and sides. (c) Diffuse oral leukoplakia, a condition in which the roof of the mouth, the gums, lips, and cheeks are covered with an opaque white, sometimes smooth, sometimes fissured, rugose layer. In this form the tongue may be spared. The visible mucosa of the lips, occasionally the genital mucosa and the pelves of the kidneys may be involved.

While appearing spontaneously, the condition is most common in heavy smokers, and has been called smoker's tongue. Epithelioma occasionally starts from the localized patches. Many of the patients have had syphilis, but the condition does not yield, as a rule, to specific treatment.

Leukoplakia is a very obstinate affection. Irritants, such as tobacco and very hot food, should be avoided. Local treatment with corrosive sublimate solution (1,200) or chromic-acid solution (1 per cent.) has been recommended. The propriety of active local treatment is doubtful. Papillomatous outgrowths should be cut off or cauterized. The X-rays may be tried. The most extensive form may disappear spontaneously.

The glossy flat atrophy of the posterior part of the tongue, described by Virchow, is in a majority of instances of syphilitic origin. Scars may give an irregular appearance to the surface. Symmers found this smooth atrophy in 55 of 75 post mortems in syphilitic subjects.

Hyperæsthesia of the Tongue.—A very distressing affection, seen chiefly in women at or beyond the menopause, occurs as a sensation of burning felt at the top over the dorsum, along the edges or sometimes over the entire organ. On examination nothing is to be seen; there is no swelling, and there may be no irritation about the teeth. It is a very obstinate affection. Some cases are due to chronic streptococcal glossitis with the organisms in the sub-epithelial layer and difficult to reach. Painting with iodine or in some cases the application of the X-rays may give relief.

Fetor oris.—The practitioner is frequently consulted for foul breath and is daily made aware of its prevalence. All unconscious, he is himself often a subject of the condition, to the disgust of his patients. The following are a few of the more important causes: (a) In connection with indigestion and associated catarrhal disturbances in the mouth, pharynx, and stomach. The breath is "heavy." A simple mouth-wash and a mercurial purge suffice to remove it. In more serious disease of the stomach the breath may be foul, and occasionally, in sloughing cancer, horribly striking. (b) Local conditions in the mouth: (1) All the forms of stomatitis. Smokers should remember

that, apart from the smell of tobacco, their breath in the morning is usually, to say the least, "heavy." (2) Pyorrhœa alveolaris. This is the most common cause of foul breath in adults, and is almost constantly present after middle life, causing a perfectly distinctive odor. To test for its presence draw a bit of stout thread or the edge of a sheet of paper high up between the teeth and the gums and then smell it. Proper mouth hygiene and treatment by a dentist are needed. (c) Tonsillar diseases. In the crypts of the tonsils the epithelial débris accumulates, and, invaded by micro-organisms, gradually forms the little round or triangular bodies, which can be squeezed out of the lacunæ, and when pressed smell like Limburger cheese. The fetor oris from this cause is quite distinctive. To test the presence in child or adult, smell the finger after it has been rubbed firmly upon the tonsil. Local treatment is needed. (d) Decayed teeth, the foul odor of which is quite distinct from that of pyorrhœa or chronic tonsillitis. (e) Respiratory. Many diseases of the nose, larynx, bronchi, and lungs are associated with foul breath. (f) Hæmic. The halitus—the expired air from the lung—may be impregnated with odors from the blood. Of this there are many well-known instances. Pyorrhœa alveolaris and chronic lacunar tonsillitis are the two most common causes of foul breath.

Oral Sepsis.—To William Hunter, of Charing Cross Hospital, is due the credit of insisting upon the importance of the mouth as the chief channel of entrance of the pyogenic organisms, and as itself the seat of septic processes. Necrosed teeth, pyorrhœa alveolaris, gingivitis, alveolar or apical abscess, etc., are present in many people. A systemic infection may follow or the general health may be lowered by the continuous production of pus. In extensive pyorrhœa alveolaris the daily amount of pus is considerable, and there can be no question that it has a debilitating influence on the general health and is sometimes associated with a moderate anæmia and a pasty complexion. Hunter describes septic gastritis and septic enteritis as common sequences; indeed, he regards appendicular, pleuritic, gall-bladder and pyelitic inflammations as forms of "medical sepsis" due largely to infection from the mouth. Severe anæmia, myocarditis, endocarditis and certain types of nephritis and forms of arthritis may be due to oral or dental infection.

There is no question of the importance of the subject, and we should insist upon scrupulous cleanliness of the mouth and teeth. Dental floss should be used as well as the toothbrush. We should have less delicacy in telling our friends in whom the odor of the breath reveals the presence of pyorrhœa. It is a difficult condition to cure but much may be done to keep it under control. Vaccines have been used, sometimes with success. If possible, the patient should be referred to a dentist who is specially competent to deal with it. The tartar should be removed and antiseptic mouth-washes used frequently. Hydrogen peroxide (1 to 4) or equal parts of tincture of iodine and alcohol may be applied locally. A saturated solution of thymol is an effective mouth-wash. The toothbrush and dental floss should be used at least twice daily.

Affections of the mucous glands are not very common. In catarrhal troubles in children and in measles they may be swollen. They are enlarged and very prominent in Mikulicz's disease, with chronic symmetrical enlarge-

ment of the salivary and lachrymal glands. There is a singular affection of the mucous glands of the lips, chiefly of the lower, with much swelling and infiltration known as macrochilia. It was described by Volkmann, and has been called Bälz's disease. The mucous glands are enlarged, the ducts much dilated, and on pressure a mucoid or muco-purulent secretion may exude. The skin over the lips may be reddened and swollen. There may be adenoma of the mucous glands. Some cases of "double lip" are due to syphilis.

Torus palatinus.—This term is applied to a protrusion in the mid-line of the hard palate which probably develops *in utero* or shortly after birth, and it is found in females more often than in males, does not cause any symptoms and those having it are unaware of the fact unless they are told. It is easily recognized by inspection. It has been regarded as a sign of tuberculosis, of syphilis, of pulmonary osteo-arthritis and of degeneracy, without any evidence. It is a congenital anomaly without any particular significance.

B. DISEASES OF THE SALIVARY GLANDS

Supersecretion (Ptyalism).—The normal amount of saliva varies from 2 to 3 pints in the twenty-four hours. The secretion is increased during the taking of food and in the physiological processes of dentition. A great increase (*ptyalism*) occurs (1) occasionally in mental and nervous affections and in rabies; (2) occasionally in the acute fevers, particularly in small-pox; (3) in stomatitis, mouth infection and painful conditions of the mouth; (4) with irritation of the œsophagus, gastric hyperacidity, occasionally with ulcer and disease of the pancreas; (5) during gestation, usually early, though it may persist through the entire course; (6) occasionally at each menstrual period; and (7) it is a common effect of certain drugs, mercury, the iodine compounds and jaborandi, also muscarine and tobacco. Salivation may be present without any inflammation of the mouth. In some patients there may be constant spitting or swallowing which becomes a habit. The constant secretion is annoying and if it is swallowed digestive disturbance may follow. In some patients, especially in the neurotic type, there may be complaint of a foul taste to the saliva, apart from that due to drugs.

In *treatment*, correction of the cause is important. Belladonna or atropine controls the secretion; the effective dose has to be found for each patient. Bromides may be helpful. The use of milk of magnesia both internally and as a mouth wash is often useful. Sometimes the use of a bitter solution, such as quinine, as a mouth wash gives temporary relief if there is an unpleasant taste.

Xerostomia (Deficient Salivary Secretion; Dry Mouth).—In this condition, first described by Jonathan Hutchinson, the secretions of the mouth and salivary glands are suppressed. The tongue is red, sometimes cracked, and quite dry; the mucous membrane of the cheeks and of the palate is smooth, shining, and dry; and mastication, deglutition, and articulation are very difficult. There is often an unpleasant taste. A majority of the cases are in women, and in several instances have been associated with nervous phenomena. The general health, as a rule, is unimpaired. In *treatment* the diet

should be that which tends to stimulate the flow of saliva. Acids and a bitter tonic before meals are useful. Care should be taken to keep the mouth thoroughly clean. The free use of glycerin or vaseline locally is sometimes of value and jaborandi or pilocarpine can be given cautiously.

Inflammation of the Salivary Glands.—(a) *Specific Parotitis.* (See Mumps.) (b) *Symptomatic parotitis* occurs:

(1) In the course of the infectious fevers—typhus, typhoid, pneumonia, pyæmia, etc. It was a common complication of the fevers during the great war. In ordinary practice it occurs oftenest in typhoid fever. It is the result of infection by the blood or the salivary duct. The process is usually intense and may progress to suppuration. It is, as a rule, an unfavorable indication in the course of a fever. Parotitis may occur in secondary syphilis.

(2) In connection with injury or disease of the abdomen or pelvis. Of 101 cases, "10 followed injury or disease of the urinary tract, 18 were due to injury or disease of the alimentary canal, and 23 were due to injury or disease of the abdominal wall, the peritoneum, or the pelvic cellular tissue. The remaining 50 were due to injury, disease, or temporary derangement of the genital organs." By temporary derangement is meant slight injuries or natural processes—a slight blow on the testis, the introduction of a pessary, menstruation. The infection probably takes place through the duct.

(3) In association with facial paralysis, as in a case of fatal peripheral neuritis described by Gowers; in diabetes and chronic metallic poisoning.

Uveoparotid fever is characterized by long-continued slight fever, chronic enlargement of the parotid gland and inflammation of the uvea. Some cases are tuberculous. Treatment of the gland by radium or X-rays is useful.

Treatment.—In the infectious diseases rigid cleanliness of the mouth is an important preventive measure. For the parotitis an ice bag often aids or hot fomentations may be applied. A free incision should be made *early* if there are signs of suppuration.

(c) *Chronic parotitis,* a condition in which the glands are enlarged, rarely painful, may follow inflammation of the throat or mumps. Salivation may be present. It may be due to lead, mercury, or potassium iodide. It occurs also in chronic nephritis and in syphilis. The cases at the Johns Hopkins clinic have been reported by C. P. Howard (*Internat. Clinics*, xix, 1). It may be associated with xerostomia. The parotid and submaxillary glands are affected with equal frequency. In one case the swelling recurred over a period of 20 years (Grieg).

Tumors.—(a) *Mikulicz's Disease.*—In this remarkable affection, described in 1888, there is a chronic, indolent, painless, symmetrical enlargement of the salivary and lachrymal glands which may last for several years. In some cases the process is tuberculous or luetic. The gland substance itself may not be disturbed, but there is a great infiltration of the interstitial connective tissue. In one case the lachrymal glands were replaced by fibrous tissue. In some cases the blood presents the picture of leukæmia. In America the disease has been seen chiefly in negroes. The enlargement may subside after an acute fever. Good results have followed the use of arsenic iodide and the X-rays. There is no tendency to recurrence after removal.

(b) *Gaseous Tumors of Steno's Duct and of the Parotid Gland.*—In glass-blowers and musicians who play wind instruments Steno's duct may become

inflated with air and form a tumor the size of a nut or of an egg. Some have contained a mixture of air, saliva, and pus. In rare cases there are gaseous tumors of the glands, which give a sensation of crepitation on palpation.

(c) *Mixed Tumor of the Parotid Gland*.—A variety of tumors are described, the majority being benign. The parotid is enlarged, firm, painless and enlarges slowly. Occasionally the growth becomes malignant.

C. DISEASES OF THE PHARYNX

Circulatory Disturbances.—(a) *Hyperæmia* is common in acute and chronic affections of the throat, and is frequently seen as a result of the irritation of tobacco smoke, and from the constant use of the voice. Venous stasis is seen in valvular disease of the heart, and in mechanical obstruction of the superior vena cava by tumor or aneurism. In aortic insufficiency the capillary pulse may sometimes be seen, and the intense throbbing of the internal carotid may be mistaken for aneurism.

(b) *Hæmorrhage* is found in association with bleeding from other mucous surfaces, or is due to local causes—granulations or varicosities. It may be mistaken for hæmorrhage from the lungs or stomach. Sometimes the patient finds the pillow stained in the morning with bloody secretion. The condition is rarely serious and requires only suitable local treatment. Occasionally hæmorrhage takes place into the mucosa, producing a pharyngeal hæmatoma. A condition of the uvula resembling hæmorrhagic infarction may occur.

(c) *Œdema*.—An infiltrated œdematous condition of the uvula and adjacent parts is not very uncommon in conditions of debility, in profound anæmia, and in nephritis. The uvula is sometimes enormously enlarged from this cause whence may arise difficulty in swallowing or in breathing.

Acute Pharyngitis (*Sore Throat; Angina Simplex*).—The entire pharyngeal structures, often with the tonsils, are involved. The condition may follow cold or exposure. In other instances it is associated with constitutional states, such as gout or digestive disorders. The patient complains of uneasiness and soreness in swallowing, of a feeling of tickling and dryness in the throat, together with a constant desire to hawk and cough. Frequently the inflammation extends into the larynx and produces hoarseness. Not uncommonly it is only part of a general naso-pharyngeal catarrh. The process may pass into the Eustachian tubes and cause slight deafness. There may be stiffness of the neck with enlarged and painful lymph-glands. The constitutional symptoms are rarely severe. The disease sets in with a chilly feeling and slight fever; the pulse is increased in frequency. Occasionally the febrile symptoms are more severe, particularly if the tonsils are specially involved. The examination of the throat shows general congestion of the mucous membrane, which is dry and glistening, and in places covered with sticky secretion. The uvula may be much swollen.

Acute pharyngitis lasts only a few days and requires mild measures. A calomel and saline purge is useful. The nose and throat may be sprayed with a simple saline solution. Cold compresses or an ice bag may be applied to the neck. If the tonsils are involved and the fever is high, acetyl salicylic acid or sodium salicylate may be given.

Vincent's Angina.—This affects the tonsil and is regarded as due to the fusiform bacillus and spirillum of Vincent occurring together. The onset is usually gradual with general malaise and fever, and sometimes pain in swallowing. There is usually only slight pain but sometimes this is severe. The breath is offensive and usually one tonsil shows a patch of membrane which can be readily detached, leaving an ulcer. The soft palate or pillars of the fauces may be involved. The glands on the affected side are swollen and tender. It may involve the gums causing an ulcerated stomatitis ("trench mouth") with severe discomfort, especially on chewing, and fetor of the breath. The *diagnosis* is aided by the finding of spirilla and the fusiform bacilli in smears, sometimes the latter in cultures. The absence of the diphtheria bacillus is important in excluding diphtheria. Syphilis may give difficulty but the more acute features and the course are of assistance, as well as the Wassermann reaction. In treatment arsphenamine solution (1-10), silver salts or hydrogen peroxide may be applied locally. A mouth wash of sodium perborate (1-50 solution) or potassium permanganate (1-2500) may be used. Neo-arsphenamine intravenously usually has a marked effect but is only necessary in severe cases. Infected teeth and tonsils should be removed after the acute features are over.

ph. leucocytes (Leuk.)
Agranulocytic Angina.—Cases of ulcerative angina with curious features have been reported under this designation. The disease occurs most often in women and usually runs a rapidly fatal course. The onset is sudden with fever and the presence of ulcers on the tonsils and pharynx, and sometimes on the larynx, gums and tongue, which spread rapidly. The regional lymph nodes are usually not enlarged. Jaundice occurs in some cases. The blood shows no changes in the red cells but the leucocytes are greatly reduced in number to below 1500 and sometimes below 1000. There is marked reduction in the granular cells which may be entirely absent both in the blood and bone marrow. The liver, spleen, and lymph nodes are not affected. In some cases the ulceration occurs on the genitals. The local lesions show an absence of reaction. In treatment, the use of 70 per cent. alcohol as a gargle and repeated blood transfusions have seemed useful.

Chronic Pharyngitis.—This may follow repeated acute attacks. It is very common in persons who smoke or drink to excess, and in those who use the voice very much, such as clergymen, hucksters, and others. It is frequently associated with chronic nasal catarrh. The naso-pharynx and the posterior wall are the parts most frequently affected. The mucous membrane is relaxed, the venules are dilated, and roundish bodies, from 2 to 4 mm. in diameter, reddish in color, project to a variable distance beyond the mucous membrane and represent proliferation of lymph tissue about the mucous glands. There may be a dry glistening state of the pharyngeal mucosa, known as *pharyngitis sicca*. The pillars of the fauces and the uvula are often much relaxed. The secretion forms at the back of the pharynx and is removed only by repeated efforts at hawking. There is usually irritation or discomfort felt in the throat.

In the *treatment* special attention must be paid to the general health. If possible, the cause should be ascertained. The condition is frequent in smokers, and cannot be cured without stopping the use of tobacco. The use of food either too hot or too much spiced should be forbidden. When it

depends upon excessive exercise of the voice, rest should be enjoined. In many of these cases change of air and tonics help very much. In the local treatment, gargles, sprays and pastilles of various sorts give temporary relief, but when the hypertrophic condition is marked the spots should be destroyed by the galvano-cautery. Infected tonsils should be removed, sinus infection treated if present, and any diseased condition of the nose remedied if possible.

Ulceration of the Pharynx.—(a) *Follicular*.—The ulcers are usually small, superficial, and generally associated with chronic catarrh.

(b) *Syphilitic*.—Most frequently painless and situated on the posterior wall of the pharynx, they occur in the secondary stage as small, shallow excavations with the mucous patches. In the tertiary stage they are due to erosion of gummata, and in healing they leave whitish cicatrices.

(c) *Tuberculous*.—Not very uncommon in advanced cases of pulmonary tuberculosis, if extensive, they form one of the most distressing features of the disease. The ulcers are irregular, with ill-defined edges and grayish-yellow bases. The posterior wall of the pharynx may have an eroded, worm-eaten appearance. These ulcers are, as a rule, intensely painful. Occasionally the primary disease is about the tonsils and the pillars of the fauces.

(d) *Ulcers* occur in connection with pseudo-membranous inflammation, particularly the diphtheritic. In cancer and in lupus ulcers are also present.

(e) *Ulcers* are met with in certain of the fevers, particularly in typhoid.

In many instances the diagnosis of the nature of pharyngeal ulcers is very difficult. The tuberculous and cancerous varieties are readily recognized, but doubt frequently arises as to the syphilitic character of an ulcer. In many instances the local conditions may be uncertain. Other evidences of syphilis should be sought for, and the patient placed on mercury and iodide of potassium, under which specific ulcers usually heal with great rapidity.

Acute Infectious Phlegmon of the Pharynx.—This is a severe infection, usually due to streptococci. Under this Senator describes cases with difficulty in swallowing, soreness of the throat, and sometimes hoarseness, the neck enlarges, the pharyngeal mucosa becomes swollen and injected, the fever is high with severe toxæmia and the inflammation passes on rapidly to suppuration. The symptoms are very intense. The swelling of the pharyngeal tissues early reaches such a grade as to impede respiration. Similar symptoms may be produced by foreign bodies in the pharynx. The patient should be at rest and given as much nourishment and water as possible. Hot or cold applications should be made to the neck. Anti-streptococcic serum may be given. Tracheotomy may be necessary and incisions should be made if there is pus formation.

Retro-pharyngeal Abscess.—The acute form occurs: (a) In healthy children between six months and two years of age. The child becomes restless, the voice changes; it becomes nasal or metallic in tone, and there are pain and difficulty in swallowing. Inspection of the pharynx reveals a projecting tumor in the middle line, or, if not visible, it is felt, on palpation, projecting from the posterior wall. (b) As a not infrequent sequel of the fevers, particularly scarlet fever and diphtheria. The treatment consists in free incision, avoiding the chance of aspiration of the pus. The chronic form occurs with caries of the bodies of the cervical vertebræ. The diagnosis is readily made, as the

projecting tumor can be seen, or felt with the finger on the posterior wall of the pharynx. This should be opened through the neck.

Angina Ludovici (*Ludwig's Angina; Cellulitis of the Neck*).—This occurs as a secondary inflammation in the specific fevers, particularly diphtheria and scarlet fever; it may occur idiopathically or result from trauma. It is probably always a streptococcus infection which spreads rapidly. The swelling at first is most marked in the submaxillary region of one side. The symptoms are, as a rule, intense, and, unless early and thorough surgical measures are employed, there is great risk of systemic infection. The various acute septic inflammations of the throat—acute oedema of the larynx, phlegmon of the pharynx and larynx, and angina Ludovici—“represent degrees varying in virulence of one and the same process” (Semon). The treatment is surgical and free incisions should be made.

D. DISEASES OF THE TONSILS

I. SUPPURATIVE TONSILLITIS (QUINSY)

Etiology.—Acute suppuration of the tonsillar or peritonsillar tissues is met with most frequently in young persons with chronic tonsillitis, sometimes as a sequence of the acute form, sometimes as a result of exposure.

Symptoms.—The constitutional disturbance is very great. The temperature rises to 104° or 105° F., and the pulse ranges from 110 to 130. Nocturnal delirium is not uncommon. The prostration may be extreme. There is no local disease of similar extent which so rapidly exhausts the strength of a patient. Soreness and dryness of the throat, with pain on swallowing, are the symptoms of which the patient first complains. One or both tonsils may be involved. They are enlarged, firm to the touch, dusky red and oedematous, and the contiguous parts are also much swollen. The swelling of the glands may be so great that they meet in the middle line, or one tonsil may even push the uvula aside and almost touch the other gland. The salivary and buccal secretions are increased. The glands of the neck enlarge, the lower jaw is fixed, and the patient is unable to open his mouth. In from two to four days the enlarged gland becomes softer, and fluctuation can be felt by placing one finger on the tonsil and the other at the angle of the jaw. The abscess points usually toward the mouth, but in some cases toward the pharynx. It may burst spontaneously, affording instant relief. Suffocation has followed the rupture of a large abscess and the entrance of the pus into the larynx. When the suppuration is peritonsillar and extensive, the internal carotid artery may be opened; but these are very rare accidents. The diagnosis is usually easy, but a gumma or newgrowth may be regarded as quinsy.

Occasionally a small focus of deep-seated suppuration is the cause of a fever lasting for weeks or months.

Treatment.—Hot applications in the form of poultices and fomentations may be more comfortable than the ice-bag. Codein or morphia may be required for pain. Irrigation of the throat with a hot alkaline solution usually gives some relief. The area should be opened when fluctuation is distinct. The progress may be shortened and the patient spared several days of suffering

if an incision is made early. A curved bistoury, guarded nearly to the point with plaster or cotton, is the most satisfactory instrument. There are cases in which, before suppuration takes place, the swelling is so great that the patient is threatened with suffocation. In such instances the tonsil must be excised or tracheotomy performed. Patients with this affection require a nourishing liquid diet, and during convalescence iron in full doses.

Early removal of the tonsils should be done when there are recurring attacks, and thorough local treatment should be given to the naso-pharynx.

II. CHRONIC TONSILLITIS AND ADENOIDS

(Chronic Naso-pharyngeal Obstruction; Mouth-breathing; Aprosodia)

Under this heading will be considered also hypertrophy of the adenoid tissue in the vault of the pharynx, sometimes known as the pharyngeal tonsil, as the affection usually involves both the tonsils proper and this tissue, and the symptoms are not to be differentiated. Chronic enlargement of the tonsillar ring is an affection of great importance, and may influence in an extraordinary way the mental and bodily development of children.

The lacunæ are really nothing but culture tubes in which an extraordinary number of organisms grow, the dominant ones being streptococci. Other organisms are the staphylococcus, pneumococcus, and Micrococcus catarrhalis. Normally these organisms are kept at bay by the epithelium and by the leucocytes which constantly stream out from the lymphoid tissues. But in catarrhal conditions or by abrasion, the organisms may spread into the substance of the tonsil or pass the capsule and cause a general infection. Chronic tonsillar infection is a frequent source of metastatic infection.

Etiology.—"Adenoids" have become recognized as one of the most common and important affections of childhood, occurring most frequently between the fifth and tenth years. The systematic inspection of school children has more than anything else forced upon the profession and the public the importance of tonsillar infection and adenoids as influencing seriously bodily and mental growth, disturbing hearing and furnishing a focus for the development of pathogenic organisms. Few children escape altogether. In many it is a trifling affair, easily remedied; in others it is a serious and obstinate trouble, taxing the skill and judgment of the specialist. It is not easy to say why the conditions have become so prevalent. In the United States it is attributed to the dry, hot air of the houses, in England to the cold, damp climate. In winter nearly all the school children in England have the "snuffles," and a considerable proportion of them adenoids. American children may be especially prone, but the disease is very prevalent in England. Adenoids may be associated with slight enlargement of the lymph-glands, thymus and spleen in the condition of lymphatism.

Morbidity Anatomy.—The tonsils are enlarged, due to multiplication of all the constituents of the glands. The lymphoid elements may be chiefly involved without much development of the stroma. In other instances the fibrous matrix is increased, and the organ is then harder, smaller, firmer, and is cut with much greater difficulty.

The adenoids, which spring from the vault of the pharynx, form masses varying in size from a small pea to an almond. They may be sessile, with broad bases, or pedunculated. They are reddish in color, of moderate firmness, and contain numerous blood-vessels. "Abundant, as a rule, over the vault, on a line with the fossa of the Eustachian tube, the growths may lie posterior to the fossa—namely, in the depression known as the fossa of Rosenmüller, or upon the parts which are parallel to the posterior wall of the pharynx. The growths appear to spring in the main from the mucous membrane covering the localities where the connective tissue fills in the inequalities of the base of the skull" (Harrison Allen). The growths are most frequently papillomatous with a lymphoid parenchyma. Hypertrophy of the pharyngeal adenoid tissue may be present without great enlargement of the tonsils proper. Chronic catarrh of the nose usually coexists.

Symptoms.—The direct effect of adenoids is the establishment of mouth-breathing. The indirect effects are deformation of the thorax, changes in the facial expression, sometimes marked mental alteration, in certain cases stunting of the growth, and deafness in a great many subjects. Woods Hutchinson suggested that the embryological relation of these structures and the pituitary body may account for the interference with development. The establishment of *mouth-breathing* is the symptom which first attracts the attention. It is not so noticeable by day, although the child may present the characteristic vacant expression. At night the child's sleep is greatly disturbed; the respirations are loud and snorting, and there are sometimes prolonged pauses, followed by deep, noisy inspirations. The pulse may vary strangely during these attacks, and in the prolonged intervals may be slow, to increase greatly with the forced inspirations. The *alæ nasi* should be observed during sleep, as they are sometimes much retracted during inspiration, due to a laxity of the walls, a condition readily remedied by the use of a soft wire dilator. Night terrors are common. The child may wake up in a paroxysm of shortness of breath. Sometimes these attacks are of great severity and the dyspnoea may suggest pressure of enlarged glands on the trachea. Sometimes there is a nocturnal paroxysmal cough of a troublesome character, usually excited by lying down. Children with adenoids are specially liable to bronchitis. The thin, ill-nourished mouth-breathing child with deformed chest, cough and scattered bronchial râles is a familiar figure in tuberculosis dispensaries.

When the mouth-breathing has persisted for a long time definite changes result in the face, mouth, and chest. The facies is so peculiar and distinctive that the condition may be evident at a glance. The expression is dull, heavy, and apathetic, due in part to the fact that the mouth is habitually open. In long-standing cases the child is stupid-looking, responds slowly to questions, and may be sullen and cross. The lips are thick, the nasal orifices small and pinched-in, the superior dental arch narrowed and the roof of the mouth considerably raised. Carious teeth are common.

The remarkable alterations in the *shape* of the *chest* in connection with enlarged tonsils were first carefully studied by Dupuytren (1828), who evidently fully appreciated the great importance of the condition. He noted "a lateral depression of the parietes of the chest consisting of a depression, more or less great, of the ribs on each side, and a proportionate protrusion of the sternum in front." J. Mason Warren (Medical Examiner, 1839) gave

an admirable description of the constitutional symptoms and the thoracic deformities induced by enlarged tonsils. These, with the memoir of Lambron (1861), constitute the most important contributions to our knowledge on the subject. Three types of deformity may be recognized:

(a) THE PIGEON OR CHICKEN BREAST is the most common form, in which the sternum is prominent and there is a circular depression in the lateral zone (Harrison's groove), corresponding to the attachment of the diaphragm. The ribs are prominent anteriorly and the sternum is angulated forward at the manubrio-gladiolar junction. As a mouth-breather is watched during sleep one can see the lower and lateral thoracic regions retracted during inspiration by the action of the diaphragm.

(b) BARREL CHEST.—Some children, the subject of chronic naso-pharyngeal obstruction, have recurring attacks of asthma, and the chest may be gradually deformed, becoming rounded and barrel-shaped, the neck short, and the shoulders and back bowed. A child of ten or eleven may have the thoracic conformation of an old man with emphysema.

(c) THE FUNNEL BREAST (*Trichterbrust*).—This remarkable deformity, in which there is a deep depression at the lower sternum, has excited much controversy as to its mode of origin. In some instances, at least, it is due to obstructed breathing due to enlarged tonsils or adenoid vegetations. In two children, seen while the condition was in process of formation, during inspiration the lower sternum was forcibly retracted, so much so that at the height the depression corresponded to that of a well-marked "*Trichterbrust*." In repose, the lower sternal region was distinctly excavated.

The voice is altered and acquires a nasal quality. The pronunciation of certain letters is changed, and there is inability to pronounce the nasal consonants *n* and *m*. Some lay stress upon the association of mouth-breathing with stuttering.

The hearing is impaired, usually owing to the extension of inflammation along the Eustachian tubes and the obstruction of their orifices. In some instances it may be due to retraction of the drums, as the upper pharynx is insufficiently supplied with air. Naturally the senses of taste and smell are much impaired. There may be little or no nasal catarrh or discharge, but the pharyngeal secretion of mucus is increased. Children do not notice this, as the mucus is usually swallowed, but older persons expectorate it with difficulty.

Among other symptoms are headache, by no means uncommon, general listlessness, and an indisposition for physical or mental exertion. Habit-spasm of the face has been described in connection with it and permanent relief has been afforded by the removal of the adenoid vegetations. Enuresis is occasionally an associated symptom. The influence upon the mental development is striking. Mouth-breathers are usually dull, stupid, and backward. It is impossible for them to fix the attention for long at a time, and to this impairment of the mental function Guye, of Amsterdam, gave the name *aproxia*. Headaches, forgetfulness, inability to study without discomfort are frequent symptoms of this condition in students. There is more than a grain of truth in the aphorism *shut your mouth and save your life*, which is found on the title-page of Captain Catlin's celebrated pamphlet on mouth-breathing (1861), to which he attributed all the ills of civilization.

A symptom especially associated with enlarged tonsils is fetor of the breath.

The inspissated secretion undergoes decomposition and the little cheesy masses may sometimes be squeezed from the crypts of the tonsils. In some cases of chronic enlargement the cheesy masses may be deep in the tonsillar crypts; and if they remain for a prolonged period lime salts are deposited and a tonsillar calculus is produced. The *lingual tonsil* may be a source of infection, excite cough, or cause sensations referred to the nose or larynx.

Children with chronic tonsillitis and adenoids are especially prone to take cold and to recurring attacks of acute tonsillitis. They may be more liable to diphtheria, and in them the anginal features in scarlet fever are always more serious. The ultimate results of untreated adenoid hypertrophy are important. In some cases the vegetations disappear, leaving an atrophic condition of the vault of the pharynx. Neglect may lead to the so-called Thornwaldt's disease, in which there is a cystic condition of the pharyngeal tonsil and constant secretion of muco-pus.

Other conditions which may result from chronic throat and nose infection, including sinusitis, especially in children, are bronchial asthma, bronchitis and bronchiectasis. In patients over 50 years of age chronic tonsillar infection is often associated with apical infection of teeth.

Diagnosis.—Enlarged tonsils are readily seen on inspection of the pharynx. Infected tonsils may be small; careful local examination should be made. There may be no great enlargement of the tonsils and nothing apparent at the back of the throat even when the naso-pharynx is completely blocked with adenoid vegetations.

Treatment.—The decision as to the removal of tonsils is sometimes a difficult one. There has been much discussion of the subject and a great deal of nonsense talked. A focus of infection in a tonsil should be regarded exactly as a focus elsewhere. It is a good rule to get rid of any focus of infection if there are no contraindications. If there is chronic tonsillar infection with local symptoms, recurring acute attacks, injury to the ears or general infection (rheumatic fever, endocarditis, arthritis, nephritis, etc.) it is wise to advise removal. The surface condition is no guide as to the absence of infection in the deeper parts. Age should not be regarded in the decision as to removal if there is infection. Treatment by radium or X-rays cannot be regarded as an equal substitute in the majority of cases. Important complications may follow the removal—hæmorrhage, hyperpyrexia, infarction and abscess of the lungs, general sepsis, cerebro-thrombosinosis, subcutaneous emphysema, or death from status lymphaticus. Applications of iodine and solutions of silver salts are of service in the milder grades, but it is a waste of time to apply them to chronically infected glands. The galvanocautery is of service in cases of enlarged tonsils when there is objection to removal, but should not be regarded as an effective substitute.

The treatment of adenoid growths should be thorough. Parents should be told frankly that the affection is serious, one which impairs the mental not less than the bodily development of the child. In spite of the thorough ventilation of this subject by specialists, practitioners do not appear to have grasped the full importance of this disease and are far too apt to temporize and unnecessarily postpone radical measures. Special examination should be made of the thymus gland, as if it is enlarged the operation should be postponed. In the state of lymphatism death during anæsthesia has occurred.

Usually the child soon breathes through the nose but sometimes the habit of mouth-breathing persists. In these cases a chin strap can be readily adjusted, which the child wears at night. In severe cases it may take months of careful training before the child can speak properly. An all-important point in the treatment of lesions of the naso-pharynx (and, indeed, in the prevention of this unfortunate condition) is to increase the breathing capacity of the chest by systematic exercises.

Throughout the entire treatment attention should be paid to hygiene and diet, and cod-liver oil and iodide of iron may be administered with benefit.

E. DISEASES OF THE ŒSOPHAGUS

I. ACUTE ŒSOPHAGITIS

Etiology.—Acute inflammation occurs: (a) In the catarrhal processes of the specific fevers; more rarely as an extension from infection of the pharynx. (b) As a result of intense mechanical or chemical irritation, produced by foreign bodies, very hot liquids, or strong corrosives. The swallowing of household lye is a common cause in young children. (c) In the form of pseudo-membranous inflammation in diphtheria, and occasionally in pneumonia, typhoid fever, and pyæmia. (d) As a pustular inflammation in small-pox. (e) In connection with local disease, particularly cancer either of the tube itself or extension to it from without. And lastly acute œsophagitis, occasionally with ulceration, may occur spontaneously in sucklings.

Morbid Anatomy.—It is extremely rare to see redness of the mucosa, except when chemical irritants have been swallowed. More commonly the epithelium is thickened and has desquamated, so that the surface is covered with a fine granular substance. The mucous follicles are swollen and occasionally there are small erosions. In the pseudo-membranous inflammation there is a grayish exudate, usually limited in extent, at the upper portion. In phlegmonous inflammation the mucous membrane is greatly swollen with purulent infiltration of the submucosa. Gangrene occasionally supervenes. There is a remarkable fibrinous or membranous œsophagitis, most frequent in the fevers, in which casts of the tube may be vomited.

Symptoms.—In the milder forms of catarrhal inflammation there are usually no symptoms. Pain in deglutition is always present in severe inflammation of the œsophagus. A dull pain beneath the sternum is also common. The presence of a foreign body is indicated by dysphagia and spasm with the regurgitation of portions of food. Later, blood and pus may be ejected. It is surprising how extensive disease in the œsophagus may be without producing much pain or great discomfort, except in swallowing. The intense inflammation which follows the swallowing of corrosives, when not fatal, gradually subsides, and often leads to cicatricial contraction and stricture. Severe grades of inflammation with ulceration are followed by cicatricial stenosis. In the cases in which there is danger of contraction preventive treatment should be carried out to prevent severe stenosis. The possibility of a foreign body should be remembered. An X-ray study and œsophagoscopy are important.

Treatment.—This is unsatisfactory, particularly in the severer forms. The slight catarrhal cases should be given fluid diet and bismuth in water. Vaseline may be placed frequently on the back of the tongue. When the dysphagia is intense it is best not to give food by the mouth, but to give glucose solution (5 per cent.) and water by the bowel. Fragments of ice may be given, and later, demulcent drinks. External applications of cold often give relief. With severe injury to the œsophagus, gastrostomy should be done at once.

Chronic œsophagitis occurs when there is retention of food in the œsophagus, and may be associated with chronic pharyngitis or gastritis; ulceration may result. Discomfort or pain is felt, occasionally going through to the back. In treatment, irritant substances should be avoided and dry bismuth subnitrate placed on the tongue. Local treatment, especially the use of silver salts, should be applied through the œsophagoscope.

Ulceration.—This occurs with acute œsophagitis. Syphilis, tuberculosis, neoplasm, severe infections and aneurism may be responsible. The majority of cases in adults are due to neoplasm. Peptic ulcer occurs at the lower end of the œsophagus. The usual complaints are of substernal pain and difficulty in swallowing; hæmorrhage and perforation may occur. The diagnosis is made by the history, general features and direct inspection by the œsophagoscope. Treatment must depend on the cause to some extent. Rest of the œsophagus, bland diet, bismuth on the tongue and local endoscopic treatment are important. Gastrostomy may be necessary.

Œsophageal Varices.—Associated with chronic heart-disease and more frequently with a cirrhotic liver, the œsophageal veins may become distended and varicose. Rupture of these varices is one of the commonest causes of hæmatemesis in cirrhosis of the liver and in enlarged spleen. The blood may pass per rectum alone.

II. SPASM OF THE ŒSOPHAGUS

(*Œsophagismus*)

This is met with in nervous patients and hypochondriacs, also in chorea, epilepsy, and especially hydrophobia. It is sometimes associated also with the lodgment of foreign bodies, or with cases in which a patient has swallowed a foreign body and thinks it has stuck. For weeks there may be spasm, due perhaps to autosuggestion, though the bougie passes freely. The idiopathic form is found in females of a marked neurotic habit, but may also occur in elderly men. It may be present only during pregnancy. The patient complains of inability to swallow solid food, and in extreme instances even liquids are rejected. The attack may come on abruptly, and be associated with emotional disturbances and with substernal pain. The condition is rarely serious, though it may persist for years. Spasm of the cricopharyngeus is often the cause of globus hystericus. In this spasmodic stenosis there is difficulty in starting the swallowing of the bolus of food. Spasm of the lower end of the gullet often occurs at the level of the diaphragm and is regarded as cardio-spasm. It may be the cause of a remarkable fusiform dilatation of the œsophagus.

The *diagnosis* is not difficult, particularly in young persons with marked nervous manifestations. The X-ray study is important. Great care must be taken to exclude cancer and stenosis.

In some cases a cure is at once effected by the passage of the œsophagoscope. The general neurotic condition also requires special attention. Atropine in full doses is sometimes helpful.

Paralysis of the œsophagus is a very rare condition, due most often to central disease, particularly bulbar paralysis. It may be peripheral in origin, as in diphtheritic paralysis. Occasionally it occurs in hysteria. The essential symptom is dysphagia. Cardio-œsophageal relaxation can be recognized only by the X-ray study.

III. STENOSIS OF THE ŒSOPHAGUS

This results from: (a) Congenital stenosis of the œsophagus. There are several forms of complete stricture; in one there is complete occlusion with the two parts connected by a fibrous cord or with no connection at all. In another the upper portion ends in a pouch and the lower portion opens into the trachea or a bronchus, forming a fistula; in another there may be the upper part only or the œsophagus may be closed by a membrane. Vinson (1923) found 146 reported cases and added one. Partial congenital stricture also occurs, often remedied by gradual dilatation. (b) The cicatricial contraction of healed ulcers, usually due to corrosive poisons, occasionally to syphilis, and in rare instances after the fevers. Of particular importance is the frequency of stenosis in young children from swallowing lye. (c) Tumors in the wall. (d) External pressure by aneurism; enlarged lymph-glands, enlarged thyroid, other tumors, and sometimes by pericardial effusion. The majority of cases of stenosis of the œsophagus in adult and later life are due to carcinoma, usually of the squamous cell form. Adenocarcinoma occurs in the lower œsophagus or extends from the stomach.

The *cicatricial stricture* may occur anywhere in the gullet, and the narrowing may be extreme, so that only small quantities of food can trickle through, or the obstruction may be quite slight. When the stricture is low down the œsophagus is dilated and the walls are usually much hypertrophied. When the obstruction is high in the gullet, the food is usually rejected at once, whereas, if it is low, it may be retained and a considerable quantity collects before it is regurgitated. Any doubt as to its having reached the stomach is removed by the alkalinity of the material ejected and the absence of the characteristic gastric odor. Auscultation of the œsophagus is sometimes of service. The patient takes a mouthful of water and the auscultator listens along the left of the spine opposite the seventh dorsal spine. The normal œsophageal *bruit* may be heard later than seven seconds, the normal time, or there may be a loud splashing, gurgling sound. The secondary murmur, heard as the fluid enters the stomach, may be absent. The bismuth meal and the fluoroscope make the diagnosis easy. In pressure stenosis, careful clinical and X-ray study usually make the diagnosis. The œsophagoscope determines the locality. A bougie should not be used owing to the danger of perforation. It is well always, as a precautionary measure, to examine carefully for aneur-

ism, which may produce the symptoms of organic stricture. When the narrowing is extreme there are always emaciation and marked dehydration. In *treatment* it is important to give sufficient food and water. If the obstruction is marked, gastrostomy should be done. Various methods of dilatation are employed. In pressure stenosis the causal condition should be treated if possible.

IV. CANCER OF THE ŒSOPHAGUS

This is more frequent in middle life and in males. At first confined to the mucous membrane, the cancer gradually increases and soon ulcerates. The lumen of the tube is narrowed, but when ulceration is extensive in the later stages the stricture may be less marked. Dilatation of the tube and hypertrophy of the walls usually take place above the cancer. There may be marked spasm. The ulcer may perforate the trachea or a bronchus, the lung, the pleura, the mediastinum, the aorta or one of its larger branches, the pericardium, or erode the vertebræ. The recurrent laryngeal nerves are not infrequently implicated. Perforation of the lung produces, as a rule, local gangrene.

Symptoms.—*Dysphagia* is usually an early symptom but may be absent throughout. If present it is progressive and becomes extreme, so that the patient emaciates rapidly. Regurgitation may take place at once after swallowing; or, if the cancer is situated near the stomach, it may be deferred for ten or fifteen minutes, or even longer if the tube is much dilated. The rejected materials may be mixed with blood and may contain cancerous fragments. Feelings of discomfort on swallowing, often regarded as neurotic, increased secretion or cough (sometimes due to the overflow of secretion) may be early symptoms. In persons over fifty years of age persistent difficulty in swallowing accompanied by rapid emaciation usually indicates œsophageal cancer. Sudden transient attacks of difficulty in swallowing may occur or there may be no symptoms until there is sudden stenosis with an advanced growth. The cervical lymph-glands are frequently enlarged and may give early indications of the nature of the trouble. Pain may be persistent or present only when food is taken. It may be deep-seated or referred to the back. In certain instances the pain is very great. The latent cases are very rare. Bronchitis and broncho-pneumonia are common terminal events. Death usually occurs within 3 to 9 months after the onset of symptoms.

Diagnosis.—It is important to exclude pressure from without, as by aneurism or tumor. The history enables us to exclude cicatricial stricture and foreign bodies. In every patient over 40 years of age, œsophageal symptoms demand the consideration of neoplasm. The œsophagoscope is of great aid. Fragments of tissue may be removed through the tube for examination. The X-ray examination is of service both in showing the presence of a growth and its position.

Treatment.—In most cases milk and liquids can be swallowed, but supplementary nourishment and water should be given by the rectum. Intubation of the œsophagus may be useful for a time. As spasm may play a part, atropine is often useful by causing relaxation. The use of radium and X-rays may prolong life and reduce discomfort. When there is difficulty in feeding the

patient gastrostomy should be performed at once, as it gives comfort and prolongs the patient's life. With improved surgical technique and early diagnosis we may hope that cure may be possible; otherwise the outlook is hopeless.

V. RUPTURE OF THE ŒSOPHAGUS

(a) Rupture may occur as a result of violent vomiting after a full meal, or when intoxicated. In 1914 Walker collected 22 cases, 20 of which were in males. In every case the rupture was at the lower end. Boerhaave described the first case in Baron Wassenaer, who "broke asunder the tube of the œsophagus near the diaphragm, so that, after the most excruciating pain, the elements which he swallowed passed, together with the air, into the cavity of the thorax, and he expired in twenty-four hours." (b) In a few cases the rupture has occurred in a diseased and weakened tube, near the scar of an ulcer, for example. (c) Post-mortem softening—œsophago-malacia—must not be mistaken for it. In spontaneous rupture the rent is clean-cut; in malacia it is rounded and the margins are softened. The contents of the stomach may be in the pleura.

VI. DILATATIONS AND DIVERTICULA

Stenosis of the gullet is followed by secondary dilatation of the tube above the constriction and great hypertrophy of the walls. Idiopathic dilatation, so called, is due to phrenospasm (cardiospasm) or associated with contraction of the stomach as in scirrhus cancer. The tube may attain extraordinary dimensions, as in the specimen shown in 1904 to the Association of American Physicians by Kinnicut. Difficulty in swallowing, usually most marked with solids, and regurgitation of food are the most common symptoms. Pain occurs in some patients. There may also be difficulty in breathing from pressure. The diagnosis has to be made from cancer, in which the X-ray study and the examination by the œsophagoscope are important. It is important to begin treatment as early as possible. Certain foods may have a special influence and should be avoided. Atropine, in proper dosage for the patient, may be useful. Special treatment for the causal condition should be given. Gastrostomy should be done before the general nutrition suffers.

Diverticula are of two forms: (a) Pressure diverticula, which are most common at the junction of the pharynx and gullet, on the posterior wall. Owing to weakness of the muscles at this spot, local bulging occurs, which is gradually increased by the pressure of food, and finally forms a saccular pouch. (b) The traction diverticula on the anterior wall near the bifurcation of the trachea result, as a rule, from the extension of inflammation from the lymph-glands with adhesion and subsequent cicatricial contraction, by which the wall of the gullet is drawn out. The diagnosis of these forms is readily made by the X-rays. They can be successfully extirpated.

A rare and remarkable condition is the œsophago-pleuro-cutaneous fistula. In one patient fluids were discharged at intervals through a fistula in the

right infra-clavicular region, which communicated with a cavity in the upper part of the pleura or lung. The condition had persisted for more than twenty-five years.

F. DISEASES OF THE STOMACH

I. ACUTE GASTRITIS

(*Simple Gastritis; Acute Gastric Catarrh; Acute Dyspepsia*)

Etiology.—Acute gastritis occurs at all ages, and is usually traceable to errors in diet. It may follow the ingestion of too much food or from taking unsuitable articles, which either themselves irritate the mucosa or decompose, and so excite an acute dyspepsia. A frequent cause is the taking of food which has begun to decompose, particularly in hot weather. In children these fermentative processes are very apt to excite enteritis as well. Another common cause is the abuse of alcohol, and the acute gastritis which follows a drinking-bout is one of the most typical forms. The tendency to gastric disturbance varies much in different individuals, and, indeed, in families. We recognize this in using the expressions a “delicate stomach” and a “strong stomach.”

Morbid Anatomy.—Beaumont’s study of St. Martin’s stomach showed that in acute catarrh the mucous membrane is reddened and swollen, less gastric juice is secreted, and mucus covers the surface. Slight hæmorrhages or even small erosions may occur. The submucosa may be somewhat cedematous. Microscopically the changes are chiefly noticeable in the mucous and peptic cells, which are swollen and more granular, and there is an infiltration of the intertubular tissues with leucocytes.

Symptoms.—In mild cases the symptoms are those of slight indigestion—an uncomfortable feeling in the abdomen, headache, depression, nausea, eructations, and vomiting, which usually gives relief. The tongue is heavily coated and the saliva is increased. In children there are intestinal symptoms—diarrhœa and colicky pains and often fever. The duration is rarely more than twenty-four hours. In the severer forms the attack may set in with a chill and febrile reaction, in which the temperature rises to 102° or 103° F. The tongue is furred, the breath heavy, and vomiting is frequent. The ejected substances, at first mixed with food, subsequently contain much mucus and bile-stained fluids. There may be constipation, but very often there is diarrhœa. The urine presents the usual febrile characteristics and there is a heavy deposit of urates. The abdomen may be somewhat distended and tender in the epigastric region. Herpes may appear on the lips. The attack may last from one to three days, and occasionally longer. The examination of the vomitus shows, as a rule, absence of hydrochloric acid, the presence of lactic and fatty acids, and marked increase in the mucus.

Diagnosis.—The ordinary afebrile gastritis is readily recognized. The acute febrile form is so similar to the initial symptoms of some infectious diseases that it is impossible for a day or two to make a diagnosis, particularly in the cases which have come on spontaneously and independently of

an error in diet. Some of these resemble closely an acute infection; the symptoms may be intense, and if the attack sets in with severe headache and delirium, the case may be mistaken for meningitis. When the abdominal pains are intense the attack may be confounded with gall-stone colic or rupture of an ulcer. Gastric crises in tabes have been mistaken for acute gastritis.

Duodenitis.—The *simple* or *catarrhal* form is often associated with acute gastritis. There is colicky pain usually two or three hours after meals, felt to the right of the midline, with frequent nausea but rarely vomiting. By the duodenal tube shreds or streaks of mucus may be obtained which are not mixed with the duodenal contents. The process may be part of a general enteritis. *Suppurative* duodenitis is rare and has followed trauma. A local peritonitis may follow and the signs are those of an acute inflammatory condition. *Ulcerative* duodenitis may follow a burn or occur with infectious diseases.

Treatment.—Mild cases recover spontaneously in twenty-four hours, and require no treatment other than a dose of castor oil in children or of blue mass in adults. In severer forms, if there is much gastric distress, vomiting should be promoted by warm water or the stomach tube may be employed. A dose of calomel, 2 to 3 grains (0.13 to 0.2 gm.), should be given, and followed, after some hours, by a saline cathartic. If there is eructation of acid fluid, bicarbonate of soda and bismuth may be given. The stomach should have absolute rest, and it is a good plan to cut off all food for a day or two. The patient may be allowed soda water and ice freely. It is well not to attempt to check the vomiting unless it is excessive and protracted. Recovery is usually complete, though repeated attacks may lead to chronic gastritis.

Phlegmonous Gastritis; Acute Suppurative Gastritis.—The disease is due to infection of the submucosa, probably through a minute abrasion. Males are more frequently affected than females, and most of the cases are in comparatively young people. In a majority of the instances in which the examination has been made streptococci have been present, but the pneumococcus has been found in a few cases. The disease is rare; Leith was able to collect only 85 cases. There is a widespread suppurative infiltration of the submucosa, with great thickening of the walls. Sometimes there is a localized abscess, with tumor, which may burst into the stomach or into the peritoneum.

The important symptoms are pain, high fever, vomiting, dry tongue, all the features of a severe infection, and sometimes jaundice. The vomitus may contain pus. A diagnosis is rarely made; occasionally there is a large tumor mass to be felt. The outlook is very serious, as peritonitis usually follows.

Toxic Gastritis.—This most intense form of gastritis is excited by the swallowing of concentrated mineral acids or strong alkalis, or by such poisons as phosphorus, corrosive sublimate, ammonia, arsenic, etc. In the non-corrosive poisons, such as phosphorus, arsenic, and antimony, the process consists of an acute degeneration of the glandular elements and hæmorrhage. With powerful poisons the mucous membrane is extensively destroyed, and may be converted into a brownish-black eschar. In the less severe grades there may be areas of necrosis surrounded by inflammatory reaction, while the submucosa is hæmorrhagic and infiltrated.

SYMPTOMS.—These are intense pain in the mouth, throat and stomach, salivation, great difficulty in swallowing, and constant vomiting, the vomitus being bloody and sometimes containing portions of the mucous membrane.

The abdomen is tender, distended, and painful on pressure. In the most acute cases symptoms of collapse supervene; there is restlessness, and sometimes convulsions. There may be albumin or blood in the urine, and petechiæ may occur on the skin. When the poison is less intense, the sloughs may separate, leaving ulcers, which too often lead, in the œsophagus to stricture, in the stomach to chronic atrophy, and finally to death from exhaustion.

DIAGNOSIS.—The diagnosis of toxic gastritis is usually easy, as inspection of the mouth and pharynx shows, in many instances, corrosive effects, while the examination of the vomit may indicate the nature of the poison.

TREATMENT.—In poisoning by acids, magnesia should be administered in milk or with egg albumen. When strong alkalies have been taken, dilute acids should be administered. If the patient is seen early, lavage should be used. For the severe inflammation which follows the stronger poisons palliative treatment is alone available, and morphia should be given freely.

Diphtheritic or Membranous Gastritis.—This is met with occasionally in diphtheria, but more commonly as a secondary process in typhus or typhoid fever, pneumonia, pyæmia, small-pox, and occasionally in debilitated children. The exudation may be extensive and uniform or in patches. The condition is not recognizable during life, unless the membranes are vomited.

Mycotic and Parasitic Gastritis.—Fungi occasionally grow in the stomach and excite inflammation. One of the most remarkable cases is that reported by Kundrat, in which the favus fungus occurred in the stomach and intestine. In cancer and dilatation of the stomach the sarcinæ and yeast fungi probably aid in maintaining the chronic gastritis. As a rule, the gastric juice is capable of killing the ordinary bacteria. Anthrax bacilli may produce swelling of the mucosa and ulceration. Acute emphysematous gastritis may be of mycotic origin. The larvæ of certain insects may excite gastritis.

II. CHRONIC GASTRITIS

(Chronic Catarrh of the Stomach; Chronic Dyspepsia)

Definition.—A condition of disturbed digestion associated with increased mucus formation, qualitative or quantitative changes in the gastric juice, and with alterations in the mucosa. The term chronic gastritis is used loosely to designate a variety of gastric disorders, in many of which there are no actual changes in the mucous membrane. If the term is restricted to organic changes, it is a comparatively rare primary disease. Clinically, it is not easy to draw the line between chronic gastritis and functional disturbance.

Etiology.—The causes may be classified as follows: (a) *Dietetic.* Un-suitable or improperly prepared food, and the persistent use of irritating articles of diet. The use in excessive quantity of hot bread, hot cakes, and pie is a fruitful cause, particularly in the United States, and also the use in excess of tea or coffee, and, above all, of alcohol. Under this heading come habits of eating at irregular hours or too rapidly, and imperfectly chewing the food. "The platter kills more than the sword." Another cause is the abuse of tobacco, particularly chewing. (b) *Constitutional Causes.* Anæmia chronic tuberculosis, gout, diabetes, and nephritis are often associated with

chronic gastritis. (c) *Local Conditions*: (1) of the stomach, as in cancer, ulcer, and dilatation; (2) conditions of the portal circulation, causing chronic engorgement of the mucous membrane, as in cirrhosis, chronic heart disease, and certain chronic lung affections. (d) *Oral sepsis*, particularly pyorrhœa, is regarded as a common cause, the evidence for which is chiefly of the *propter hoc* kind—the improvement in digestion after attention to the mouth. (e) The association of gastritis with disease elsewhere, as appendicitis or cholecystitis, may be due to a common source of infection. (f) The chronic form may follow acute gastritis.

Morbid Anatomy.—In simple chronic gastritis the organ is usually enlarged, the mucous membrane pale gray in color, and covered with closely adherent, tenacious mucus. The veins are large, patches of ecchymosis are not infrequently seen, and in the chronic catarrh of portal obstruction and of chronic heart-disease small hæmorrhagic erosions. Toward the pylorus the mucosa may be irregularly pigmented, and present a rough, wrinkled, mammillated surface, which may be so prominent that writers have described it as *gastritis polyposa*. The membrane may be thinner than normal and much firmer. The minute anatomy shows the picture of a parenchymatous and an interstitial inflammation. The mucous membrane may undergo complete atrophy and be represented by a smooth cuticular membrane.

Symptoms.—The affection persists for an indefinite period, and, as is the case with most chronic diseases, changes from time to time. Many of the symptoms are due to functional disturbance. The disease itself probably does not cause many symptoms. The appetite is variable, sometimes greatly impaired, at others very good. Among early symptoms are feelings of distress or oppression after eating, which may become aggravated and amount to actual pain. When the stomach is empty there may also be a painful feeling. The pain differs in different cases, and may be trifling or of extreme severity. When localized and felt beneath the sternum or in the præcordial region it is known as heart-burn or sometimes cardialgia. There is pain on pressure over the stomach, usually diffuse and not severe. The tongue is coated, and the patient complains of a bad taste in the mouth. The tip and margin of the tongue are very often red and with this there may be an increase in the salivary and pharyngeal secretions. Nausea is an early symptom, and is particularly apt to occur in the morning hours. It is not nearly so constant as in cancer of the stomach, and in mild grades of the affection it may not occur at all. Eructation of gas, which may continue for some hours after taking food, is a prominent feature in cases of so-called flatulent dyspepsia, and there may be marked distention of the intestines. With the gas, bitter fluids may be brought up. Vomiting, which is not very frequent, occurs either immediately after eating or an hour or two later. In the chronic catarrh of old toppers a bout of morning vomiting is common, in which a slimy mucus is brought up. The vomitus consists of food in various stages of digestion and mucus; chemical examination shows the presence of abnormal acids, such as butyric, or even acetic, in addition to lactic acid, while hydrochloric acid, if present, is much reduced in quantity. The digestion may be delayed, but usually there is not much disturbance of motility.

Constipation is usually present, but in some instances there is diarrhœa, and undigested food passes rapidly through the bowels. The urine is often

scanty, high-colored, and deposits a heavy sediment of urates. Of other symptoms headache is common, and the patient feels constantly out of sorts, indisposed for exertion, and low-spirited. Trousseau called attention to the occurrence of vertigo, a marked feature in certain cases. The pulse is small, sometimes slow, and there may be palpitation of the heart. Fever does not occur. Cough is sometimes present, but the so-called stomach cough of chronic dyspeptics is in all probability dependent upon pharyngeal irritation.

The Gastric Contents.—The fasting stomach usually contains much mucus. Pathogenic organisms are almost constantly found, of which streptococci are the most important. The appearance of the secretions may be much delayed but they gradually appear. The HCl is usually diminished, though it may be normal. In some cases the free HCl may be absent, while in the advanced forms of atrophy of the mucosa there may be neither acids nor ferments. Mucus is not present in atrophic gastritis.

The symptoms of atrophy of the mucous membrane of the stomach, without contraction of the organ, are very complex, and do not present a uniform picture. The majority of the cases present the symptoms of an aggravated chronic dyspepsia, often of such severity that cancer is suspected. The persistent distress after eating, the vomiting, and the gradual loss of flesh and strength may lead to the diagnosis of cancer. The clinical picture may be that of a severe anæmia.

Diagnosis.—It is well in any patient complaining of gastric symptoms to decide first whether there is primary organic disease of the stomach or whether the condition is secondary to disease elsewhere. This involves a general study which should always be made thoroughly. It is easy to fix one's attention on the area of symptoms and fail to recognize the site of the cause. The organic causes of chronic stomach disturbance are usually readily recognized. Carcinoma may give the greatest difficulty, but repeated careful studies of the gastric contents and the X-ray findings usually remove any doubt. With this excluded the problem is to decide whether there is any other organic change in the stomach, such as ulcer or dilatation, or whether the symptoms are purely functional. If evidence of gastritis is found the next problem is whether the condition is primary or secondary. In this the history and the general study of the patient are important.

The study of the gastric contents is usually of great aid. The presence of mucus is evidence for gastritis. The symptoms in functional gastric disturbances are usually more irregular. Careful search should be made for disease elsewhere, either general or local. The relation of symptoms to food is usually marked in gastritis.

Chronic duodenitis is usually secondary to gastritis so that the symptoms are not clearly localized. There is discomfort felt to the right of the midline with nausea. The symptoms are usually some hours after meals. There may be vomiting of mucoid material. There may be signs of pancreatic insufficiency. The study of the duodenal contents is important in diagnosis.

Treatment.—Much of what is said here applies to the group of "dyspepsias" whether due to actual gastritis or not. The discovery and proper treatment of the cause is often the essential point. In the majority of cases the symptoms are secondary to disease elsewhere and in them the treatment is largely of the primary condition. Usually there is no difficulty in differen-

tiating the ordinary catarrhal and the nervous varieties. Two important questions should be asked of every dyspeptic—first, as to the time taken at his meals; and, second, as to the quantity he eats. A number of all cases of disturbed digestion comes from hasty and imperfect mastication and from overeating. Especial stress should be laid upon the former point. In some instances it will alone suffice to cure dyspepsia if the patient will eat slowly. The second point is of even greater importance. People habitually eat too much, and it is probably true that a greater number of maladies arise from excess in eating than from excess in drinking. Chittenden's researches have shown that we require much less nitrogenous food to maintain health.

(a) GENERAL AND DIETETIC.—A careful and systematically arranged dietary is the first, sometimes the only, essential in the treatment of chronic dyspepsia. It is impossible to lay down rules applicable to all cases but in general the diet should be low in protein and largely carbohydrate. Individuals differ extraordinarily in their capability of digesting different articles of food, and there is much truth in the old adage, "One man's food is another man's poison." The individual preferences for different articles of food should be permitted in the milder forms. Physicians have probably been too arbitrary in this direction, and have not yielded sufficiently to the intimations given by the appetite and desires of the patient. The amount of fluid depends on the condition of the stomach as regards motility. If there is delay in emptying the amount should not exceed 1500 c. c. daily. Usually a glass of hot water, slowly sipped, before meals, especially breakfast, is advisable.

A rigid milk diet may be tried. "Milk and sweet sound Blood differ in nothing but in Color: *Milk is Blood*" (George Cheyne). In the forms associated with nephritis and chronic portal congestion, as well as in many instances in which the dyspepsia is part of a neurasthenic or hysterical trouble, this plan in conjunction with rest is most efficacious. If milk is not digested well it may be diluted one-third with soda water or Vichy, or 5 to 10 grains of carbonate of soda, or a pinch of salt may be added to each tumblerful. In many cases milk from which the cream has been taken is better borne. Buttermilk is particularly suitable, but can rarely be taken for so long a time alone, as patients tire of it more quickly than they do of ordinary milk. Not only can the general nutrition be maintained on this diet, but patients sometimes increase in weight, and the gastric symptoms disappear. It should be given at fixed hours and in definite quantities gradually increased. The amount varies, but at least 3 to 5 pints should be given in the twenty-four hours. This diet is not, as a rule, well borne when there is a tendency to dilatation of the stomach. The milk may be peptonized but it is impossible to feed a chronic dyspeptic in this way. The stools should be carefully watched, and if more milk is taken than can be digested it is well to supplement the diet with eggs and dry toast or biscuits.

In a large proportion of the cases it is not necessary to annoy the patient with strict dietaries. It may be sufficient to cut off certain articles of food. Thus, if there are acid eructations or flatulency the farinaceous foods should be restricted, particularly potatoes and the coarser vegetables. A fruitful source of indigestion is hot bread and this as well as pancakes, pies and tarts, with heavy pastry, and fried articles of all sorts, should be strictly

forbidden. As a rule, white bread, toasted, is more readily digested than bread made from the whole meal. Persons differ very much in this respect, and the whole wheat or brown bread is most digestible for many people. Sugar and sweet articles of food should be taken in great moderation or avoided altogether. Many instances of indigestion are due to the prevalent practice of eating largely of ice-cream at all hours. One of the most powerful enemies of the American stomach is the soda-water fountain with its many "messes," which has usurped so important a place in the apothecary shop.

Fats, with the exception of a moderate amount of good butter, very fat meats, and thick, greasy soups should be avoided. Ripe fruit in moderation is often advantageous, particularly when cooked. Bananas are not, as a rule, well borne. Alcohol and condiments should be prohibited for a time; it is better if they are given up entirely.

In the matter of special articles of food it is impossible to lay down rigid rules, and it is the common experience that one patient with indigestion will take with impunity the articles which cause distress to another.

Another detail of importance is the general hygienic management. These patients are often introspective, dwelling in a morbid manner on their symptoms, and much inclined to take a despondent view of their condition. Very little progress can be made unless the physician gains their confidence from the outset. Their fears and whims should not be made too light of or ridiculed. Systematic *exercise*, carefully regulated, particularly when, as at watering places, it is combined with a restricted diet, is of special service. Rest after meals is often useful. Change of air and occupation, a prolonged sea voyage, or a summer in the mountains will sometimes cure the most obstinate dyspepsia.

(b) **TEETH.**—These should be put in good condition and mouth infection receive attention. The patient should be taught proper dental hygiene, especially the use of dental floss.

(c) **MEDICINAL.**—The special measures may be divided into those which attempt to replace elements which are lacking in the digestive juices and those which stimulate the organ. In the first group come the hydrochloric acid and ferments, which are so freely employed. The former is the most important. It is the ingredient in the gastric juice most commonly deficient. It is best given as the dilute acid taken in somewhat larger quantities than are usually advised. Ewald advised large doses—of from 90 to 100 drops—at intervals of fifteen minutes after the meals. Probably from 30 to 60 drops is sufficient. The prolonged use of it does not appear to be hurtful.

Nitrate of silver is useful in some cases, used in solution in lavage (1 to 1,500 or 1 to 2,000), or in pill form, one-eighth to one-fourth of a grain three times a day. Argyria has resulted after its protracted use.

The digestive ferments are extensively employed. The use of pepsin may be limited to the cases of advanced mucous catarrh and atrophy of the stomach, in which it should be given, in doses of from 10 to 15 grains, with dilute hydrochloric acid a quarter of an hour after meals. Pancreatin is of equal or greater value and should be given in doses of from 15 to 20 grains, with sodium bicarbonate. It is conveniently administered in tablets, each of which contains 5 grains of the pancreatin and the soda, and of these two or three

may be taken fifteen or twenty minutes after each meal. Malt diastase is sometimes serviceable given with alkalies.

Of measures which stimulate the glandular activity lavage is the most important, particularly in the forms with the secretion of a large quantity of mucus. Lukewarm water should be used, or, if there is much mucus, a 1 per cent. salt solution, or a 3 to 5 per cent. solution of bicarbonate of soda. If there is much fermentation the 3 per cent. solution of boric acid may be used. It is best employed in the morning on an empty stomach, or in the evening some hours after the last meal, when there is much nocturnal distress and flatulency. Once a day is, as a rule, sufficient, or, in delicate persons, every second day. The irrigation may be continued until the water comes away quite clear. It is not necessary to remove all the fluid after the irrigation. While in some hands this measure has been carried to extremes, it is of value in certain cases. A substitute may be used in the form of alkaline drinks, taken slowly in the early morning or the last thing at night if there is objection to lavage.

Of medicines which stimulate the gastric secretion the bitter tonics are probably of more value in chronic gastritis than hydrochloric acid. Of these nux vomica is the most useful, though none has probably any very great stimulating action on the secretion. Histamine hydrochloride (0.25 mg. subcutaneously) is a strong stimulant of gastric secretion. Cases of true achylia should be recognized and dilute hydrochloric acid given. If a patient has been in the habit of taking light wines with his meals, the practice may be continued if moderate quantities are taken. Beer, as a rule, is not well borne.

(d) TREATMENT OF SPECIAL CONDITIONS—Flatulency.—For this careful dieting may suffice, particularly forbidding such articles as tea, pastry, and the coarser vegetables. Thorough chewing is also important. It is usually combined with pyrosis, in which the acid fluids are brought into the mouth. Bismuth and sodium bicarbonate sometimes relieve the condition. For acid dyspepsia Sir William Roberts recommended the bismuth lozenge of the British Pharmacopœia, the antacid properties of which depend on chalk and bicarbonate of soda. It should be taken an hour or two after meals, and only when the pain and uneasiness are present. The burnt magnesia is also a good remedy. Glycerin in from 20- to 60-minim doses, the essential oils, animal charcoal alone or in combination with compound cinnamon powder may be tried. If there is much pain, spirit of chloroform in 20-minim doses or a teaspoonful of Hoffman's anodyne may be used. In obstinate cases lavage is indicated and is sometimes striking in its effects. Alkaline solutions may be used. Very often flatulency is due to the swallowing of air, a habit which the patient can overcome.

Vomiting is not a feature which often calls for treatment in chronic dyspepsia; sometimes in children it is a persistent symptom. Creosote and carbolic acid in drop doses, a few drops of chloroform or of dilute hydrocyanic acid, cocaine, bismuth, and oxalate of cerium may be used. If obstinate, the stomach should be washed out daily.

Constipation is a frequent and troublesome feature and every effort should be made to remedy it without the use of purgatives. Regularity in going to stool, the taking of sufficient water especially before meals, proper exercise, and the use of agar-agar or mineral oil may be enough. If drugs are needed

the simpler laxatives should be used, such as senna, cascara and phenolphthalein. In the cases secondary to other diseases, such as renal or cardiac, the use of salines is indicated. Glycerin suppositories or the injection of a small amount of glycerin may be efficacious.

Many patients are benefited by the use of mineral waters, particularly a residence at the springs with a careful diet and systematic exercise.

III. CIRRHOSIS VENTRICULI

•Brinton described under the term *linitis plastica* a condition of diffuse sclerosis of the stomach with thickening of the walls and reduction of the lumen. It may be localized, but more commonly involves the whole organ, and a similar condition has been found in the colon, small bowel, and rectum. In one case, a patient of Dr. Drake's, Montreal, the stomach was no bigger than a cucumber; and the cæcum and part of the ascending colon showed the same thickening. The special lesion is an enormous hypertrophy of the submucosa, with atrophy of the gland elements and hypertrophy of the muscular layers, so that the wall is six to eight times the normal thickness; but, as Brinton remarks, the layers remain distinct. There are two forms, benign and malignant, which are not easy to separate without the most careful microscopic examination. Lyle collected 118 cases from the literature, more than half of which were the true plastic linitis of Brinton.

The symptoms are at first indefinite, but when well established vomiting becomes marked and there is inability to retain even small amounts of food. The presence of a sausage-shaped tumor in the epigastrium is important. Hæmorrhage may be present. The X-ray picture is of great help. The protracted history, the restriction in capacity of the stomach, and the tumor give a characteristic clinical picture. Food should be taken in the most concentrated form, in small amounts and frequently. Gastro-enterostomy is helpful if it can be done, but in the majority it is impossible; total gastrectomy has been performed in some cases.

IV. DILATATION OF THE STOMACH

ACUTE DILATATION is a very serious condition, described by Hilton Fagge, characterized by sudden onset, vomiting of enormous quantities of fluid, and symptoms of collapse. Of 102 cases collected by L. A. Conner 42 followed operation with general anæsthesia. The next largest group occurs in the course of severe diseases, especially pneumonia, or during convalescence. Cases have followed injuries, particularly of the head and spine. In 9 cases the symptoms came on after a single large meal; 6 cases were associated with spinal disease, in 3 while the patients were in a plaster of Paris jacket, and in a few cases it has come on in persons in good health. There were 74 deaths. In 69 autopsies the duodenum was found dilated in 38 cases. In a majority of cases it is due to a constriction of the lower end of the duodenum by traction on the mesenteric root, which is particularly apt to occur when there is a long mesentery and when the coil of small bowel is empty and falls into the

true pelvis. It may be due to complete loss of tone of the stomach. The *diagnosis* is usually easy—repeated vomiting of large quantities of bilious non-faecal fluid, with subnormal temperature, pain, collapse symptoms, and distended abdomen are the common features. In *treatment*, nothing should be taken by mouth and glucose (5 per cent.) and sodium bicarbonate (1 per cent.) solution given by the bowel. The stomach should be emptied repeatedly by the tube; the small tube may be left in position. Pituitrin hypodermically is worth a trial. If possible the patient should lie on the face or assume the knee-chest position. Operation has not proved very satisfactory.

CHRONIC DILATATION results from: (a) *Pyloric obstruction* due to narrowing of the orifice or of the duodenum by the cicatrization of an ulcer, hypertrophic stenosis of the pylorus (whether cancerous or simple), congenital stricture, or occasionally by pressure from without of a tumor or of a floating kidney. The pylorus may be tilted up by adhesions to the liver or gall-bladder, or the stomach may be so dilated that the pylorus is dragged down and kinked. Adhesions about the gall-bladder may extend along the adjacent parts of the stomach and hitch up the pylorus into the hilus of the liver, forming a very acute kink. In some cases there is an *intermittent* retention lasting for some hours, often due to pyloric spasm. In such cases there are usually hyperacidity and the signs of *vagotonia*. It may be associated with disease of the duodenum, gall-bladder or appendix. In some cases it seems as if pyloric spasm may lead to definite dilatation. Syphilis and pedunculated benign tumors at the pylorus are rare causes. (b) *Relative or absolute insufficiency of the muscular power* of the stomach, due to repeated overfilling of the organ with food and drink or to atony of the coats induced by chronic inflammation or the degeneration of impaired nutrition, the result of constitutional affections.

The most extreme forms are met with as a sequence of the cicatricial contraction of an ulcer. There may be considerable stenosis without much dilatation, the obstruction being compensated by hypertrophy of the muscular coats. In the group, due to atony of the muscular coats, we must distinguish between instances in which the stomach is simply enlarged and those with actual dilatation. The size of the stomach varies greatly and the maximum capacity of a normal organ Ewald places at about 1,600 c. c. Measurements above this point indicate absolute dilatation.

Atonic dilatation may result from weakness of the coats, due to repeated overdistention, to chronic catarrh of the mucous membrane, or to the general muscular debility associated with chronic wasting disorders. The combination of chronic gastric catarrh with overfeeding and excessive drinking is a common cause of atonic dilatation as is seen in diabetics, the insane, and beer-drinkers. In Germany this form is common in men employed in breweries. Possibly muscular weakness of the coats may result from disturbed innervation. It is common in cases of general neurosis, especially with visceroptosis. Dilatation of the stomach is most frequent in middle-aged or elderly persons, but is not uncommon in children, especially with rickets.

Symptoms.—In *atonic dilatation* there may be no symptoms whatever, even with a greatly enlarged organ; more frequently there are the associated features of *neurasthenia*, *enteroptosis*, and *nervous dyspepsia*; while in a

third group there may be all the symptoms of pyloric obstruction—vomiting of enormous quantities, etc.

The features of *pyloric obstruction*, from whatever cause, are usually very evident. *Dyspepsia* is present in nearly all cases, and there are feelings of distress and *uneasiness* in the stomach. The patient may complain much of hunger and thirst and eat and drink freely. The most characteristic sign is the vomiting at intervals of enormous quantities of liquid and of food, amounting sometimes to four or more litres. The material is often of a dark-grayish color, with a characteristic sour odor due to the organic acids present, and contains mucus and remnants of food. On standing it separates into three layers, the lowest consisting of food, the middle of a turbid, dark-gray fluid, and the uppermost of a brownish froth. The microscopic examination shows a large variety of bacteria, yeast fungi, and sarcinæ. There may also be fruit stones and grape seeds. The hydrochloric acid may be absent, diminished, normal, or in excess, depending upon the cause of the dilatation. The fermentation produces lactic, butyric, and, possibly, acetic acid and various gases. In the *intermittent* forms with pyloric spasm there is retention often for four to eight hours, usually with hyperacidity. Vagotonia is often present and disease of the gall-bladder, duodenum or appendix should be considered.

In consequence of the small amount of fluid which passes from the stomach there are constipation, scanty urine, and extreme dryness of the skin. The general nutrition suffers greatly; there is loss of flesh and strength, and in some cases the most extreme emaciation. The color may be retained and if there is much vomiting, there may be marked polycythæmia. Tetany may occur.

PHYSICAL SIGNS.—*Inspection.*—The abdomen may be large and prominent, the greatest projection occurring below the navel in the standing posture. In some instances the outline of the distended stomach can be plainly seen, the small curvature a couple of inches below the ensiform cartilage, and the greater curvature passing obliquely from the tip of the tenth rib on the left side, toward the pubes, and then curving upward to the right costal margin. Too much stress can not be laid on the importance of inspection. Very often the diagnosis may be made *de visu*. Active peristalsis may be seen in the dilated organ, the waves passing from left to right. Occasionally anti-peristalsis may be seen. In cases of stricture, particularly of hypertrophic stenosis, as the peristaltic wave reaches the pylorus, the tumor-like thickening can sometimes be distinctly seen through the abdominal wall. To simulate peristalsis the abdomen may be flipped with a wet towel. In many cases the outline of the dilated stomach stands out with great distinctness after inflation and waves of peristalsis are very evident.

Palpation.—The peristalsis may be felt, and usually in stenosis a tumor is evident at the pylorus. The resistance of a dilated stomach is peculiar, and has been aptly compared to that of an air cushion. A splashing sound—*clapotage*—may be obtained which is not distinctive, as it can be obtained whenever there are much liquid and air in the organ. The splashing may be very loud, and the patient may produce it himself by suddenly depressing the diaphragm, or it may be readily obtained by shaking him. The gurgling of gas through the pylorus may be felt.

Percussion.—The note is tympanitic over the greater portion of a dilated

stomach; in the dependent part the note is flat. In the upright position the percussion should be made from above downward, until a change in resonance is reached. The line of this should be marked, and the patient examined in the recumbent position, when it will be found to have altered its level. When this is on a line with the navel or below it, dilatation of the stomach may generally be assumed to exist. The fluid may be withdrawn from the stomach with a tube, and the dulness so made to disappear, or it may be increased by pouring in more fluid. In cases of doubt the organ should be inflated.

Auscultation.—The *clapotage* can be obtained readily. Frequently a curious sizzling sound is present, not unlike that heard over a soda-water bottle when first opened. It can be heard naturally, and is usually evident when the artificial gas is being generated. The heart sounds may sometimes be transmitted with great clearness and with a metallic quality.

Diagnosis.—This can usually be made without much difficulty. Emphasis should be placed on the value of inspection, particularly in combination with inflation of the stomach. Curious errors are on record, one of the most remarkable of which was the confounding of dilated stomach with an ovarian cyst; even after tapping and the removal of portions of food and fruit seeds, abdominal section was performed and the dilated stomach opened. The diagnosis of ascites has been made and the abdomen opened. The X-ray findings are distinctive. The *prognosis* depends upon the cause; it is good in simple atony, bad in cancerous stricture, fairly good in simple stricture. Surgery usually gives excellent results.

Treatment.—In the cases due to atony careful regulation of the diet and proper treatment of the associated general condition will suffice to effect a cure. Strychnine, ergot, and iron are recommended. Washing out the stomach is of great service, though we do not see such striking and immediate results in this form. In cases of mechanical obstruction the stomach should be emptied and thoroughly washed, either with warm water or with an antiseptic solution. Three important things are accomplished: The weight which distends the organ is removed; the fermenting materials are washed out; and we cleanse the inner surface of the organ. The patient can usually be taught to wash out his own stomach, and in dilatation from simple stricture the practice may be followed with great benefit. The rapid reduction in the size of the stomach is often remarkable, the vomiting ceases, food is taken readily, and in many cases the general nutrition improves rapidly. As a rule, once a day is sufficient, and it may be practised either the first thing in the morning or before going to bed. As soon as the fermentative processes have been checked lukewarm water alone should be used. In the intermittent form the use of atropine with small doses of bromide is often useful. Any lesion elsewhere in the abdomen should be properly treated.

The food should be taken in small quantities at frequent intervals, and as concentrated as possible. Fatty and starchy articles of diet are to be avoided. Liquids should be taken sparingly. In atonic cases postural treatment is often helpful and the use of an abdominal support may give great relief. The patient should sleep with the foot of the bed elevated and lie on the right side as much as possible.

Surgery should be resorted to early in cases of organic stricture; in atonic dilatation it is not advisable as the cause usually is not in the stomach.

V. THE PEPTIC ULCER, GASTRIC AND DUODENAL

The round, perforating, simple or peptic ulcer is usually single, and occurs in the stomach and in the duodenum as far as the papilla. Post mortem statistics show a great preponderance of the gastric ulcer, but the experience of surgeons has taught us that in a large majority of cases which come to operation the ulcer is outside the pyloric ring.

Erosions.—Small abrasions of the mucosa—2 to 4 mm.—usually multiple, are common, extending half way or quite through the layer. They are often called hæmorrhagic erosions from their blood-stained appearance. They are met with in the new-born, in cachectic states in children, in chronic heart and arterial disease, in cirrhosis of the liver, etc. Of no clinical importance, as a rule, occasionally an acute hæmorrhagic erosion of quite small size opens a large artery, and the patient bleeds to death. There is no difference between this condition and the acute form of the gastric ulcer.

In certain acute infections with the pneumococcus (Dieulafoy) and septic organisms there may be hæmorrhagic erosions, which occasionally prove fatal by hæmatemesis. The post-operative hæmatemesis, slight or grave, may be due to these erosions. The French have described them as if peculiar to operations for appendicitis but cases occur after all sorts of abdominal operations. It is probable that the gastric hæmorrhages which occur in connection with the throbbing aorta in neurotic women are due to these erosions.

Etiology of Peptic Ulcer.—INCIDENCE.—The disease is much more common than medical and pathological statistics indicate. The surgical work of many men has taught us that ulcer exists in many cases regarded as simple hyperchlorhydria. In two points surgical experience has completely changed our views, viz.: the incidence of ulcer in the male is greater than in the female, and duodenal is more common than gastric ulcer. In a series of 1,725 proved cases more than two-thirds were duodenal (Smithies). The incidence appears to vary in different localities, and post-mortem figures from the United States and Canada show a much lower percentage of cases (1.32) than on the Continent of Europe (5 per cent.), and in London (4.2 per cent.) (C. P. Howard). Tobacco and alcohol do not cause ulcer; they probably aggravate one which is present.

SEX.—Acute simple gastric ulcer occurs in young women more often than in males, but chronic ulcer is much more common in males. The acute forms in females seem to have greatly decreased in frequency in the United States.

AGE.—In females the largest number of cases occurred between fifteen and twenty-five; in males between thirty and fifty. It may occur in old people. E. G. Cutler studied a series of 29 cases in children. In 6 the symptoms came on immediately after birth. There were 8 cases under seven years of age, and 9 between eight and thirteen.

OCCUPATION.—Among women, anæmic dyspeptic servant girls seem very prone. Shoemakers are thought to be specially liable. It appears relatively more common in the hospital classes.

TRAUMA.—Ulcers have been known to follow a blow in the region of the stomach, but this may be coincidence.

ASSOCIATED DISEASES.—Anæmia predisposes strongly to gastric ulcer,

particularly in women. It has been found also in connection with disease of the heart, arterio-sclerosis, and disease of the liver. The tuberculous and syphilitic ulcers of the stomach have been considered. Many cases are associated with disease of the appendix and gall-bladder.

BURNS.—The duodenal ulcer may follow large superficial burns. Perry and Shaw found it in 5 of 149 autopsies in cases of burns of the skin.

INFECTION.—This is the most important factor. Any focal infection may be responsible, especially in the teeth or tonsils. In cases of other associated abdominal infections, as in the appendix or gall-bladder, both may have come from a common source, or the ulcer may be secondary to the other.

Morbid Anatomy and Pathology.—Ninety per cent. of gastric ulcers are to be found at the pyloric end; nearly all duodenal ulcers are in the first portion, and more than one-half extend up to or within three-fourths of an inch of the pylorus, while 20 per cent. involve the margin of the pyloric ring (Mayo). In explanation of the greater frequency of the ulcer just outside the pyloric sphincter it is stated that this part of the duodenum is deficient in blood supply in comparison with the other. It is thought to be a bacteriological infection of the mucosa, the source being some focus in the territory of the portal vein, particularly the appendix. Multiple ulcers may occur, 8.2 per cent. in the Mayo series. From 5 to 34 have been found. In the stomach, post mortem statistics (Welch) give, in 793 cases, 288 on the lesser curvature, 235 on the posterior wall, 69 on the anterior wall, 95 at the pylorus, 50 at the cardia, 29 at the fundus, and 27 on the greater curvature.

The acute ulcer is usually small, punched out, the edges clean-cut, the floor smooth, and the peritoneal surface not thickened. The chronic ulcer is of larger size, the margins are no longer sharp, the edges are indurated, and the border is sinuous. It may reach an enormous size, as in the one reported by Peabody, which measured 19 by 10 cm., involved all of the lesser curvature and spread over a large part of the anterior and posterior walls. The sides are often terraced. The floor is formed either by the submucosa, by the muscular layers, or, not infrequently, by the neighboring organs, to which the stomach has become attached. In healing, if the mucosa is alone involved, the granulation tissue grows from the edges and the floor and the newly formed tissue gradually contracts and unites the margins, leaving a smooth scar. In larger ulcers which have involved the muscular coat the cicatricial contraction may cause serious changes, the most important of which is pyloric narrowing and consequent dilatation of the stomach. In the case of a girdle ulcer hour-glass contraction of the stomach may be produced. Large ulcers persist for years without any attempt at healing.

Among the more serious changes which may result are the following:

PERFORATION.—This occurred in 28.1 per cent. of 1,871 cases collected by Musser. In some series (Mayo's) duodenal perforation is the more common. Perforation of the anterior wall of the stomach usually excites an acute peritonitis. On the posterior wall the ulcer penetrates directly into the lesser peritoneal cavity, in which case it may produce an air-containing abscess with the symptoms of subphrenic pyopneumothorax. In rare instances adhesions and a gastro-cutaneous fistula form, usually in the umbilical region. Fistulous communication with the colon may occur or a gastro-duodenal fistula. The pericardium may be perforated, and even the left ventricle. Perforation

into the pleura may also occur. General emphysema of the subcutaneous tissues occasionally follows perforation of a gastric ulcer.

EROSION OF BLOOD-VESSELS.—In both forms of ulcer hæmorrhage occurs in 8.1 per cent. of Musser's series of 1,871 cases. It is more common in the chronic form. Ulcers on the posterior wall may erode the splenic artery, but perhaps more frequently the bleeding proceeds from the artery of the lesser curvature. In duodenal ulcer the pancreaticoduodenal artery may be eroded, or fatal hæmorrhage may result from the opening of the hepatic artery, or more rarely the portal vein. Embolism of the artery supplying the ulcerated region has been met with; in others diffuse endarteritis. Small aneurisms have been found in the floor of the ulcers. A rare event is emphysema of the sub-peritoneal tissue, which may be extensive and even pass on to the posterior mediastinum. Jurgensen ascribes it to entrance of air into the veins, but Welch thinks it represents an invasion with the gas bacillus.

CICATRIZATION.—Superficial ulcers often heal without leaving any serious damage. Stenosis of the pyloric orifice not infrequently follows the healing of an ulcer in its neighborhood. In other instances the large annular ulcer may cause in its cicatrization an hour-glass contraction of the stomach. The adhesion of the ulcer to neighboring parts may cause much pain. The mucosa in the neighborhood of the ulcer frequently shows chronic gastritis.

PERIGASTRIC AND DUODENAL ADHESIONS.—The condition is common, as high as 5 per cent. of post-mortem records. It follows ulcer, lesions of the gall-bladder, pancreatic disease, syphilitic disease of the liver, and chronic tuberculosis. In some instances the lesions are quite extensive, and the condition has been called *plastic perigastritis*. It may be associated with hypertrophic thickening of the coats of the stomach and with chronic plastic peritonitis. In some instances the pylorus or duodenum may be narrowed as a result of the adhesions, or a sort of hour-glass stomach may be produced, or the motility of the organ is interfered with. Pain is the most constant feature, and may simulate that of gastric ulcer or hyperacidity, and may be present constantly or at intervals. It is much influenced by posture and usually relieved by pressure. Local tenderness is present in a majority of instances. The cases are chronic, the general health is but slightly affected, and there are not, as a rule, signs of gastric dilatation. A definite tumor may be present about the region of the pylorus. Chronic appendicitis and lesions of the gall-bladder are found in many cases.

MODE OF ORIGIN.—The mode of origin is unknown. The anatomical basis is an interference with the blood supply in a limited area of the mucosa, attributed to embolism, thrombosis, or spasm of the arteries. Trophic influences, bacterial necrosis of the mucosa, spasm of the muscular coat in limited areas, etc., are among the hypotheses. The present tendency is to attach much importance to the part played by infection. Hurst suggests an "ulcer diathesis" which in duodenal ulcer is associated with a hypertonic stomach, which empties rapidly, plus hyperchlorhydria, so that the duodenal bulb is kept filled with acid chyme.

JEJUNAL ULCER.—This may occur after gastro-jejunostomy, but in many cases the ulcer involves both stomach and jejunum. It is rare, as after 1,141 gastro-jejunostomies at the Mayo clinic not one developed an ulcer.

CARCINOMA AND ULCER.—There has been much difference of opinion as

to the number of cases in which carcinoma develops in an ulcer. There is no doubt of its occurrence but the percentage is probably small.

Symptoms.—The condition may be latent and only met with accidentally, post mortem. The first symptoms may be those of perforation. In the *acute ulcer* there is pain which usually comes on very soon after meals, associated with marked epigastric tenderness. Hæmatemesis, of some grade, is comparatively common and often gives the diagnosis. In the majority of cases the patient has had gastric disturbance for years and the ulcer may not be suspected until a sudden hæmorrhage. The history is almost always of an illness of long duration, usually of some years, in which there have been remissions often with complete relief from symptoms. The periodicity may be marked; the symptoms are rarely continuous. Many of the symptoms are due to associated conditions of which vagotonia is important. The ulcer alone may give few symptoms in some cases.

Digestive disturbance may be slight and trifling or of a most aggravated character. Vomiting occurs in about two-thirds of the cases, often not for two or more hours after eating. It is probably most common when the ulcer is near the pylorus. The vomitus usually contains a large amount of hydrochloric acid.

HÆMORRHAGE is present in at least one-third of all cases. A patient may feel faint and turn pale and sweat; the next day the stools may be tarry from the blood that has passed into the small bowel. The bleeding may be latent (occult). These concealed hæmorrhages are often small, and the blood is not readily seen in the vomitus or stools. These latent hæmorrhages may cause a slowly progressive anæmia. More commonly the bleeding is profuse, and the blood may be in such quantities and brought up so quickly that it is fluid, bright red in color, and quite unaltered. When it remains for some time in the stomach and is mixed with food it may be greatly changed, but the vomiting of a large quantity of unaltered blood is suggestive of ulcer. As a rule, there are only one or two attacks; in our series 7 cases had one hæmorrhage, 7 two, 11 three, 1 four, and 15 many (Howard). Profuse bleeding may occur at intervals for many years. Death may follow directly. From 16 to 18 per cent. of the fatal cases are due to it (S. and W. Fenwick).

The immediate effect of a severe hæmorrhage is anæmia, from which it may take months to rally; slight fever is common. Rare and untoward effects are convulsions, sometimes only the usual convulsions of extreme cerebral anæmia from which recovery takes place, or they may precede a hemiplegia, due probably to thrombosis. Amaurosis may follow the hæmorrhage and unfortunately may be permanent, due to degeneration of the retinal ganglion cells or to a thrombosis of the cerebral arteries or veins.

PAIN is perhaps the most constant and distinctive feature. It varies greatly in character; it may be only a gnawing or burning sensation, but the more characteristic form comes on in paroxysms, in which the pain is not only felt in the epigastrium, but radiates to the back and to the sides. In many cases the two points of epigastric pain and dorsal pain, about the level of the tenth dorsal vertebra, are very well marked. The association with the taking of food and the regular recurrence are important points. In some cases the pain has no relation to food. Except in severe attacks the pain does not usually last more than an hour and disappears before the next meal. In

many cases it appears with greatest regularity as regards time after the same kind of meal. It occurs during the digestive process and disappears when the stomach is empty. It is usually stated that when the ulcer is near the cardia the pain is apt to set in earlier, but there is no certainty on this point. Vomiting and the taking of alkali usually relieve the pain. The attacks may occur at intervals for weeks or months and then disappear entirely for a prolonged period. In the attack the patient is usually bent forward, and finds relief from pressure over the epigastric region.

TENDERNESS on pressure with rigidity is common and patients wear the waist-band very low. The tender area is often constant in its situation in the same patient. Pressure should be made with great care, as rupture of an ulcer is said to have been induced by careless manipulation.

In old ulcers with thickened bases an indurated mass may be felt in the neighborhood of the pylorus.

GASTRIC CONTENTS.—There is often evidence of some retention. The findings as to acidity vary and too much importance should not be placed on them. With marked retention there may be high acidity figures. If neoplasm has developed in an ulcer the HCl is reduced. Careful search should always be made for blood, either fresh or occult, both in the stomach contents and stools.

Certain points relating to the study of the test meal may be noted. Gastric analysis gives information of the motor and secretory functions (which may be altered by organic or functional disease) and of pathological elements, mucus, pus, blood, bacteria and cancer tissue. There is no fixed normal either for motility or secretion. We show our personality in gastric function as much as in other ways. As regards secretion our ideas as to hyperacidity have had to be revised; in general high acid figures are of less importance than low figures. There is no pathognomonic curve in any gastric condition; there are general averages. Great importance should be given to the occurrence of pathological products both in the fasting stomach and after the test meal. This is too often overlooked in a routine study.

Of general symptoms, loss of weight results from the prolonged dyspepsia, but it rarely, except in association with cicatricial stenosis of the pylorus, reaches the high grade met with in cancer. The anæmia may be extreme, and of 44 cases in the wards of the Hopkins Hospital in which blood-counts were made, the lowest was 1,902,000 per c. mm. There are instances in which the anæmia can not be explained by the occurrence of hæmorrhage. In a few instances polycythæmia is present, even after a hæmorrhage, due to concentration of the blood in association with dilatation of the stomach. In a few cases parotitis occurs, with the perforation sometimes, or after a hæmorrhage.

PERFORATION.—The acute, perforating form is much more common in women than in men. The symptoms are those of perforative peritonitis. Particular attention must be given to the prompt recognition of this accident, as early operation is so successful. Perforation may take place into the lesser peritoneum or the general peritoneal cavity, in both of which cases operation is indicated; in rare instances the ulcer may perforate the pericardium. This was the case in 10 of 28 cases in which the diaphragm was perforated (Pick). Localized, more frequently subphrenic, abscess may follow perforation.

URINE.—Albumin is occasionally present; in 14 of our series with dilatation of the stomach. Indican may be present. Acetone and diacetic acid (with syncopal attacks) have been described by Dreschfeld.

HOURLY GLASS STOMACH most frequently results from the cicatrization of an ulcer. It may follow perforation of an ulcer into the liver or pancreas. In a few cases it is congenital. The features, fairly characteristic, are thus given by Moynihan: (a) In washing out the stomach part of the fluid is lost. (b) If the stomach is washed clean, a sudden reappearance of stomach contents may take place. (c) "Paradoxical dilatation"; when the stomach has apparently been emptied, a splashing sound may be elicited by palpation of the pyloric segment. (d) After distending the stomach, a change in the position of the distention tumor may be seen in some cases. (e) Gushing, bubbling, or sizzling sounds are heard on dilatation with carbon dioxide at a point distinct from the pylorus. (f) In some cases, when both parts are dilated, two tumors with a notch or sulcus between are apparent to sight or touch. To these may be added (g) a most characteristic X-ray picture. The occurrence of hour-glass stomach due to reflex spasm must be remembered. From a hasty X-ray study it might be mistaken for the organic variety.

DUODENAL ULCER.—The onset is usually insidious and perforation may be the first indication. The first symptom may be discomfort about three hours after a meal. Later there is pain which usually appears two to three hours after meals and tends to persist until the next meal or until food or alkali is taken. It frequently wakens the patient at night. It may be associated with a feeling of hunger. The situation is generally a little above the navel, in the mid line or a little to the right, rarely to the left. Vomiting is not common but there may be regurgitation of acid fluid. Frank hæmorrhage is not common, but as a rule blood is found in the stools (occult or gross) from time to time. The appetite as a rule is good and the general condition does not show much change. The test meal may give evidence of hypermotility, which is common. The acidity of the fasting stomach is often high and after an initial fall there is a rapid rise to high figures which remain. Blood may be found in small amounts. The X-ray study usually shows hypermotility and irregularity in the duodenal cap is significant. The occurrence of long periods of freedom from symptoms is often remarkable.

Prognosis.—In statistics the acute and chronic ulcer have been considered together. The former is more amenable to medical treatment, but grave complications may occur even before the symptoms are pronounced. The chronic ulcer may last for years—ten or even twenty—with intervals of good health. Controversy as to the relative results of medical and surgical treatment is futile. Medical treatment is indicated in different conditions than surgical. In the early stages medical treatment is advisable and should have a thorough trial. With a chronic ulcer it may be a waste of time to attempt it. Many cases do well with medical treatment; others are not helped. The possibility of the development of carcinoma, while not marked, should be remembered. Surgery is not always successful, for gastro-enterostomy, which is done so often, can not be regarded as a physiological operation. The mor-

tality of the chronic ulcer in the hands of good surgeons is very low.

Diagnosis.—The acute non-indurated gastric ulcer may cause very few symptoms—nothing beyond gastric discomfort with pain. This group of cases is seen chiefly in young girls, and appears to be more common in England than in the United States. *Hæmatemesis* may be the first symptom of moment. Its occurrence or the persistent presence of blood in the gastric contents is important, cancer being excluded. A condition which may cause difficulty is *gastrostaxis*, described by Hale White. The stomach symptoms are marked, the bleeding may be profuse, but post mortem or at operation no ulcer is found. Careful inspection must be made, as fatal bleeding may come from a very small erosion.

In chronic gastric ulcer the nutrition at first may remain good, and the patient looks well. The whole complaint is of the stomach, of pain and distress, with belching and nausea or vomiting from two to four hours after meals. The special features of the recurrence of the pain after taking food, its extraordinary regularity, and the tenderness and rigidity are significant. In the early stages there is usually no alteration in secretion or motility, but sooner or later both are altered. The rhythm of gastric function is disturbed. With disturbance in motility, usually delay, the secretion is altered. The secretory findings depend partly on the extent and chronicity of the ulcer and the impairment of motility. The post-digestion secretion increases. The X-ray examination is of the greatest aid. In general the diagnosis of gastric is more difficult than of duodenal ulcer.

The presence of adhesions between the gall-bladder or liver and stomach or duodenum may cause difficulty. The symptoms are long continued, present a great variety and may suggest ulcer but in their irregularity are more like those of gall-stones. The taking of food may give relief which suggests duodenal or gastric ulcer close to the pylorus. Blood is not found in the gastric contents or stools. The X-ray study may suggest duodenal ulcer very decidedly.

Gastric Ulcer.—The relief of pain by alkalies is common in ulcer. In nervous disturbances the discomfort is apt to be irregular in occurrence and the tenderness less localized. There is absence of blood and the X-ray findings are negative. Much the same points apply to *chronic gastritis* in which pain and tenderness are usually less marked. The symptoms associated with appendicitis and gall-bladder disease may cause difficulty, especially as either may occur with ulcer, but a thorough study and especially the test meals and X-ray examination should aid.

Duodenal Ulcer.—The features are usually suggestive and as a rule the diagnosis is not difficult. The later onset of pain, its association with an empty stomach, the relief on taking food or alkali, the situation of tenderness, the test meal, findings of high acidity, and the X-ray study are important, in the diagnosis from gastric ulcer. The diagnosis from gall-bladder disease may be difficult at first, but a period of study showing the absence of the usual features of ulcer should clear the difficulty. The result of treatment may be an aid as the response is usually prompt in ulcer.

Perforation of an ulcer usually gives marked signs suggestive of an acute severe abdominal condition. The occurrence of sharp pain in the region of one or both shoulders is important. It probably results from irritation of

the diaphragm. If there is a history suggestive of ulcer the diagnosis is easier but, in any case, time should not be wasted in matters of diagnosis except to recognize that something has happened which demands immediate operation. The onset of diabetic coma with abdominal pain and collapse has been mistaken for perforation of a gastric ulcer, which in *tabes dorsalis*, on the contrary, has been missed on account of the lack of pain.

Treatment.—The main principles are as follows: First, the control of foci of infection; second, the obtaining of gastric rest so far as possible, and, third, the neutralization of acidity. Unless there are definite indications for operation, it seems wise to try the effect of medical treatment, but this should be carried out systematically. The control of *infection* demands proper treatment of any foci, especially in the mouth. The control of *gastric acidity* means that there should not be free HCl in the stomach either while food is contained there or during the night.

The patient should be at rest in bed and kept there for several weeks. In the method advised by Sippy, food is given every hour from 7 A. M. to 7 P. M. during the day. At first three ounces of a mixture of equal parts of milk and cream are given. After a few days soft eggs and cooked cereals are gradually added. These may be given alternately with and in addition to the milk and cream. The total bulk at one feeding should not exceed six ounces. Later, cream soups, bread and butter, and soft foods may be added.

To control the *acidity*, alkali is given between each feeding. This is done by giving a powder of gr. x (0.6 gm.) each of heavy calcined magnesia and sodium bicarbonate alternating with a powder of gr. x (0.6 gm.) of bismuth carbonate and gr. xxx (2 gm.) of sodium bicarbonate. In addition, after the last feeding of the day, the powders should be given every half hour for four doses or until the stomach is empty. The powders are administered in about two ounces of water. It is well to aspirate the stomach about two hours after the last feeding to be sure that it is empty. If this amount of alkali is not sufficient, more sodium bicarbonate may be given. By examining the stomach contents occasionally it can be determined whether or not the free acidity is being controlled. After some weeks the patient may be given light meals, but the taking of equal parts of milk and cream each hour should be kept up. When the hourly feedings between meals are stopped, the alkaline powder should be taken every hour for three doses after each meal. It is usually well to continue this treatment longer than may seem necessary. Neutral antacids (phosphates of calcium and magnesium—neutral and not acid phosphates) are useful. The calcium salt is slightly constipating and the magnesium salt laxative. The dose is one-half to two teaspoonfuls (Kantor).

If the ulcer has caused pyloric obstruction, as a rule a larger amount of alkali is required and it is well to empty the stomach each night about half an hour after the last powder is taken. The important thing is to give sufficient alkali to control the acidity. A careful watch over the progress should be kept and the amount of retained material noted. The emptying of the stomach the last thing at night lessens the tendency to night secretion. Regular examinations of the stool for occult blood are an important guide as to the value of the treatment. In all cases it is important to obtain the co-operation of the patient so that after he passes from immediate observation he will be careful to follow instructions.

In the method advised by Coleman, the patients are kept in bed and for three to five days no food is given by mouth (if necessary 1-3 ounces of water may be given when required). Glucose is given by the bowel (300 c. c. of a 10 per cent. solution in physiological salt solution) three or four times a day. An enema is given each morning to empty the bowel. On the fourth to sixth day, the whites of three or four eggs are given alternating with olive oil (45-75 c. c. given cold on the first day). The oil is increased to 150 c. c. a day and the eggs to six or eight. Unsalted butter may be substituted for the olive oil or cream (690 c. c. equals 150 c. c. of olive oil) may have to be given. This diet should be given for three or four weeks and food increased very carefully afterward.

Medicinal measures, apart from the alkaline treatment, are of little value. Atropine is often useful in the dosage suitable for each patient and if there is a marked nervous element bromide should be given. For the bowels salines in the morning or enemata may be used. Mineral oil is often effectual. The artificial Carlsbad salts (sulphate of sodium, 50 parts; bicarbonate of sodium, 6; chloride of sodium, 3) may be given.

The pain is usually relieved by rest, proper diet, bismuth and alkalies, and atropine. If not relieved, codein (gr. $\frac{1}{4}$ - $\frac{1}{2}$, 0.015-0.03 gm.) may be given. For very severe attacks morphia may be required, best hypodermically (gr. $\frac{1}{4}$, 0.015 gm.). In the milder attacks Hoffman's anodyne, 20 or 30 drops of spirit of chloroform, or the spirit of camphor, will give relief. Counter irritation over the epigastrium with mustard is often useful.

It is important to stop the use of tobacco and alcohol.

When the stomach is irritable, the patient should be fed per rectum. He will sometimes retain food which is passed into the duodenum through a tube. Cracked ice, olive oil, oxalate of cerium, and bismuth may be tried. When hæmorrhage occurs the patient should be put under the influence of opium as rapidly as possible. No attempt should be made to check the hæmorrhage by giving drugs by mouth; as profuse bleeding is from an eroded artery, frequently from one of considerable size, it is doubtful if acetate of lead, tannic and gallic acids, etc., have the slightest influence. The essential point is to give rest, which is best obtained by opium. Nothing should be given by the mouth except small quantities of ice. Not infrequently the loss of blood is so great that the patient faints but a fatal result is not very common. Blood serum (15-30 c. c.) may be injected intramuscularly. Transfusion is advisable in severe conditions. The patients usually recover rapidly from the hæmorrhage and require iron in full doses, which may be given hypodermically.

Surgical interference is indicated: (1) For perforation; (2) in the chronic indurated ulcer. Experience has shown that after gastro-enterostomy the ulcer may heal rapidly, and in some cases the ulcer itself may be located; (3) in all cases when the ulcer has caused persistent, mechanical interference by pyloric obstruction or hour-glass stomach; (4) in cases with recurring hæmorrhages. In young girls a single attack of hæmatemesis may be due to gastrostaxis or from a simple ulcer that heals readily, but in men severe hæmatemesis is almost always from a chronic ulcer; (5) in the perigastric adhesions after chronic ulcer operation is sometimes helpful; (6) in chronic cases in which medical treatment fails to give relief; and (7) when there is reason to suspect the development of carcinoma.

The simple non-indurated ulcer is, in the majority of cases, a medical disease. A chronic indurated form is best treated surgically. In general the surgical treatment of gastric ulcer is less satisfactory than that of duodenal ulcer.

Duodenal Ulcer.—The treatment of this is much like that of gastric ulcer but surgery may be advised with much more chance of success. In certain cases, especially if recognized early, ambulant treatment may be successful. There should be as much rest as possible and no violent exercise. The patient takes three meals a day, avoiding irritating food, and takes food between meals (such as milk alone or with an egg or cracker). A glass of milk should be kept by the bedside. If pain occurs food or an alkali should be taken.

The *after care* is important for at least two years both after medical treatment and after operation. A careful watch should be kept over the condition of the mouth. The patient should be kept to a simple diet and always eat slowly. Olive oil may be taken before meals. Patients should keep up the taking of alkali for some months and always carry some with them to take at the first sign of any discomfort. The bowels should be kept regular. It is well for the patient with duodenal ulcer to take a glass of milk in the middle of the forenoon and afternoon, and at bedtime; and also to have food or alkali by the bedside to take in the night if necessary.

VI. CANCER OF THE STOMACH

Etiology.—INCIDENCE.—In an analysis of 30,000 cases of cancer, W. H. Welch found the stomach involved in 21.4 per cent., this organ standing next to the uterus in order of frequency. Among 8,464 medical cases admitted to the Johns Hopkins Hospital, there were 150 cases of cancer of the stomach.

SEX.—The disease is more common in males but there is considerable variation in the ratio in different series.

AGE.—Of 7,000 cases (Martin) the ages were: 10-20 years, 0.08 per cent.; 20-30 years, 1.5 per cent.; 30-40 years, 8.4 per cent.; 40-45 years, 18 per cent.; 50-60 years, 28 per cent.; 60-70 years, 28 per cent., and over 70 years, 16 per cent. Of the 6 cases occurring under the thirtieth year in our series of 150 cases, the youngest was twenty-two. Congenital cancer of the stomach has been described, and cases occur in children.

RACE.—Among our 150 cases, 131 were white, 19 were negroes.

PREVIOUS DISEASES, HABITS, ETC.—A history of dyspepsia was present in only 33 cases; of these, 17 had had attacks at intervals, 11 had had chronic stomach trouble, and 5 had had dyspepsia for one or two years before the symptoms of cancer developed. Napoleon, discussing this point with his physician Antommarchi, said that he had always had a stomach of iron and felt no inconvenience until the onset of what proved to be his fatal illness.

GASTRIC ULCER.—In a small proportion, possibly 10 per cent., carcinoma develops in a previous ulcer. In only 4 cases in our series was there a history pointing to ulcer.

Morbid Anatomy.—The most common varieties of gastric cancer are the cylindrical-celled adeno-carcinoma and the encephaloid or medullary carcinoma; next in frequency is scirrhus, and then colloid cancers. With refer-

ence to the situation, Welch analyzed 1,300 cases, in which the distribution was as follows: Pyloric region, 791; lesser curvature, 148; cardia, 104; posterior wall, 68; the whole or greater part of the stomach, 61; multiple tumors, 45; greater curvature, 34; anterior wall, 30; fundus, 19.

The medullary cancer occurs in soft masses, which involve all the coats of the stomach and usually ulcerate early. The tumor may form villous projections or cauliflower-like outgrowths. It is soft-grayish-white in color, and contains much blood. The cylindrical-celled epithelioma may also form large irregular masses, but the consistence is usually firmer, particularly at the edges of the cancerous ulcers. Cysts are not uncommon in this form. The scirrhus variety is characterized by great hardness, is seen most frequently at the pylorus, where it is a common cause of stenosis. It may be combined with the medullary form. It may be diffuse, involving all parts and leading to a condition which can not be recognized macroscopically from cirrhosis. This form has also been seen in the stomach secondary to cancer of the ovaries. With the diffuse carcinomatosis there may be simultaneous involvement of the small and large intestines. The colloid cancer is peculiar in its widespread invasion of all the coats. It also spreads with greater frequency to the neighboring parts and occasionally causes extensive secondary growths in other organs. The appearance on section is very distinctive, and even with the naked eye large alveoli can be seen filled with the translucent colloid material. Ulceration is not constantly present, and there are instances in which, with most extensive disease, digestion has been but slightly disturbed.

SECONDARY CANCER OF THE STOMACH.—Of 37 cases collected by Welch, 17 were secondary to cancer of the breast. Among the first 1,000 autopsies at the Johns Hopkins Hospital there were 3 cases of secondary cancer.

CHANGES IN THE STOMACH.—Cancer at the cardia is usually associated with wasting of the organ and reduction in its size. The oesophagus may be greatly dilated. On the other hand, annular cancer at the pylorus causes stenosis with great dilatation but in rare instances the pylorus has been extremely narrowed without any increase in the size of the stomach. In diffuse scirrhus cancer the stomach may be greatly thickened and contracted. It may be displaced or altered in shape by the weight of the tumor, particularly in cancer of the pylorus; in such cases it has been found in every region of the abdomen, and even in the true pelvis. The mobility of the tumors is at times extraordinary and very deceptive, and they may be pushed into the right hypochondrium or splenic region, entirely beneath the ribs. Adhesions frequently occur, particularly to the colon, the liver, and the anterior abdominal wall.

Secondary growths in other organs are very frequent, as shown by the analysis by Welch of 1,574 cases: Metastasis occurred in the lymphatic glands in 551; in the liver in 475; in the peritoneum, omentum, and intestine in 357; in the pancreas in 122; in the pleura and lung in 98; in the spleen in 26; in the brain and meninges in 9; in other parts in 92. The lymph-glands affected are usually those of the abdomen, but the cervical and inguinal glands are not infrequently attacked, and give an important clue in diagnosis. Subcutaneous metastatic growths at the navel or beneath the skin in the vicinity are of value in diagnosis.

PERFORATION.—This occurred into the peritoneum in 17 of 507 cases of

cancer of the stomach (Brinton). In our series perforation occurred in 4 cases. When adhesions form, the most extensive destruction of the walls may take place without perforation into the peritoneal cavity. In one instance a large portion of the left lobe of the liver lay within the stomach. Occasionally a gastro-cutaneous fistula is established. Perforation may occur into the colon, the small bowel, the pleura, the lung, or the pericardium.

Symptoms.—**LATENT CARCINOMA.**—There may be no symptoms pointing to the stomach, and the tumor may be discovered accidentally after death. In a second group the symptoms of carcinoma are present, not of the stomach, but of the liver or some other organ, or there are subcutaneous nodules, or, as in one of our cases, secondary masses on the ribs and vertebrae. In a third group, seen particularly in elderly persons, there is gradual asthenia, sometimes anasarca, without nausea, vomiting, or other local symptoms.

ONSET.—As a rule this is gradual with indefinite symptoms. If there has been previous gastric disease the symptoms may be little changed or somewhat increased. If the digestion previously was normal the symptoms usually come on gradually and are not characteristic; anorexia, discomfort after meals and vomiting, perhaps with some general disturbance, such as loss of weight or anæmia. In some cases the growth progresses for some time without causing any noticeable symptoms so that when these appear in marked form, an acute onset is suggested. In some patients the onset is suggestive of pernicious anæmia. It is a good rule to suspect cancer in every patient over forty in whom gastric disturbance begins without evident cause.

GENERAL FEATURES.—**Loss of Weight.**—Progressive emaciation is one of the most constant features. In 79 of our cases in which exact figures were taken: To 30 pounds, 32 cases; 30 to 50 pounds, 36 cases; 50 to 60 pounds, 5 cases; 60 to 70 pounds, 4; over 70 pounds, 1; 100 pounds, a case of cancer at the cardiac end with obstruction to swallowing. The loss in weight is not always progressive and increase occurs under three conditions: (a) Proper dieting, with treatment of the associated catarrh; (b) in cancer of the pylorus after relief of the dilatation by lavage, operation, etc.; (c) after a profound mental impression. The visit of an optimistic consultant may be followed by a gain in weight. In Keen and D. D. Stewart's case there was a gain of seventy pounds after an exploratory operation!

Loss in strength is usually proportionate to the loss in weight. One sees sometimes remarkable vigor almost to the close, but this is exceptional.

Anæmia is present in a large proportion of all cases, and with the emaciation gives the picture of cachexia. There is often a yellow or lemon tint of the skin. The average count in 59 cases was 3,712,186 per c. mm. In only 8 cases was the count below 2,000,000, and in none below 1,000,000; in 3 the red corpuscles were above 6,000,000 per c. mm. This occurs in the concentrated condition of the blood in certain cases of cancer of the pylorus with dilatation of the stomach. The average of the hæmoglobin was 45 per cent. In only 9 was it below 30 per cent. In 62 cases there were only 18 in which the leucocytes were above 12,000 per c. mm.; in only 3 cases were they above 20,000.

Among other general symptoms may be mentioned fever, which was present at some time in 74 of our 150 cases. In only 13 of these did the temperature rise above 101°; in 2 it was above 103°. Fifteen presented fairly con-

stant elevation of temperature and 8 had sudden rises. Two patients had chills, with elevation to 103° and 104°. Chills may be associated with sup-puration at the base of the cancer.

Urine.—Albumin and casts may be found. Glycosuria, peptonuria, and acetonuria have been described. Indican is common.

Edema.—Swelling of the ankles is of frequent occurrence toward the close. With an early general anasarca in combination with extreme anæmia, the cancer is usually overlooked.

The bowels are often constipated but occasionally diarrhœa is troublesome. There are no special *cardiac symptoms*; the pulse becomes progressively weaker. Thrombosis of one femoral vein may occur, or, as in one of our cases, widespread thrombosis in the superficial veins of the body. Symptoms on the part of the nervous system are rare; consciousness is often retained to the end. *Coma* may occur, sometimes due to acidosis.

DIGESTIVE DISTURBANCES.—*Anorexia* is a frequent and valuable symptom, more constant perhaps than any other. *Nausea* is a striking feature in many cases; there is often a sudden repulsion at the sight of food. In exceptional cases the appetite is retained throughout.

Vomiting may come on early or only after the symptoms have persisted for some time. It occurred in 128 cases in our series. At first it is at long intervals but subsequently it is more frequent and may recur several times in the day. There are cases in which it comes on in paroxysms and then subsides; in other cases it sets in early, persists with great violence, and a fatal termination may follow within a few weeks. Vomiting is more frequent when the cancer involves the orifices, particularly the pylorus, in which case it is usually delayed for an hour or more after taking food. When the cardiac orifice is involved it may follow at a shorter interval. Extensive disease of the fundus or of the walls may be present without vomiting. The food is sometimes very little changed, even after it has remained in the stomach for twenty-four hours.

Hæmorrhage occurred in 36 of our 150 cases; in 32 the blood was dark and altered, in 3 it was bright red. In 2 cases vomiting of blood was the first symptom. The bleeding is rarely profuse; more commonly there is slight oozing, and the blood is mixed with, or altered by, the secretions, and, when vomited, the material is dark, the "coffee-ground" vomit. Occult blood is almost constantly present in carcinoma; in ulcer it is intermittent.

Pain, an early and important symptom, was present in 130 of our cases. It is very variable in situation and, while most common in the epigastrium, it may be referred to the shoulders, the back, or the loins. The pain is dragging, burning, or gnawing in character, and rarely occurs in severe paroxysms, as in ulcer. As a rule, it is aggravated by taking food. There is usually marked tenderness on pressure in the epigastric region. The areas of skin tenderness are referred, as Head has shown, to the region between the nipple and the umbilicus in front and behind from the fifth to the twelfth thoracic spine.

STOMACH CONTENTS.—The finding of pus and blood in the fasting stomach and pus, blood and mucus two hours after the test meal is suggestive. Diminished motility may be an early finding in pyloric cancer. There is a tendency to a downward trend of gastric secretion, the opposite of the find-

ings in gastric ulcer. The results of secondary infection and secondary gastric catarrh are added to the picture. The protein curve often shows a marked divergence from the acid curve which increases as digestion goes on and is most marked in cases of subacidity or achylia. The test for soluble albumin (Wolff-Junghans) is of value, especially two hours after the test meal. The tryptophan test and ereptic reaction are of doubtful value owing to frequent regurgitation of duodenal contents. Bacteria in large numbers occur, one, the Oppler-Boas bacillus—an unusually long non-motile form—is of diagnostic value. Blood is a most important finding; the persistent presence microscopically of red corpuscles in the early morning washings is always very suspicious. Later, when coffee-ground vomiting takes place, the macroscopic evidence is sufficient. Fragments of the new growth may be vomited or appear in the washings.

Free HCl is decreased or absent in a large proportion of all cases of cancer of the stomach. There are other conditions in which free HCl is absent, such as achylia and gastritis. Repeated studies should be made before drawing conclusions. If there has been a previous ulcer the figures may be high. The presence of lactic acid is of some value.

EXAMINATION.—Inspection.—After a preliminary survey, embracing the facies, state of nutrition, etc., particular attention is given to the abdomen. An all-important matter is to have the patient in a good light. Fullness in the epigastric region, inequality in the infracostal grooves, the existence of peristalsis, a wide area of aortic pulsation, the presence of subcutaneous nodules or small masses about the navel, and, lastly, a well-defined tumor mass—these, together or singly, may be seen on careful inspection. In 62 of the 150 cases a tumor could be seen and in 52 it descended with inspiration; in 36 peristalsis was visible; in 3 cases movements were visible in the tumor itself. In 10 cases with visible peristalsis no tumor was seen, but could be felt on palpation. The presence of subcutaneous and umbilical nodules may help. They were found in 5 of our series.

Palpation.—In 115 cases a tumor could be felt; in 48 in the epigastric region, in 25 in the umbilical, in 18 in the left hypochondriac, in 17 in the right hypochondriac region, while in 7 cases a mass descended on deep inspiration from beneath the left costal margin. These figures illustrate in how large a proportion of the cases the tumor is in evidence when the patient comes under observation. In rare cases examination in the knee-elbow position is of value. Mobility of a gastric tumor is of much importance. First, the change with respiration, a mass may descend 3 or 4 inches in deep inspiration; secondly, the communicated pulsation from the aorta, which is often suggestive in its extent; thirdly, the intrinsic movements in the hypertrophied muscularis; and fourthly, mechanical movements, with inflation or change of posture, or communicated by the hand. Tumors of the pylorus are the most movable, and in extreme cases can be displaced to either hypochondrium or pushed far down below the navel (see illustrative cases in Osler's Lectures on the Diagnosis of Abdominal Tumors). Pain on palpation is common; the mass is usually hard, sometimes nodular. Gas can at times be felt gurgling through a tumor at the pyloric region.

Percussion gives less important indications—the note over a tumor is rarely flat, more often a flat tympany. Auscultation may reveal the gurgling

through the pylorus; sometimes a systolic bruit is transmitted from the aorta, and when local peritonitis exists a friction may be heard.

Complications.—Secondary growths are common especially in the lymph nodes, liver and other adjacent organs.

Perforation may lead to peritonitis, but in 3 of our 4 cases there was no general involvement. Cancerous ascites is not uncommon. Dock called attention to the value of the examination of the fluid in such cases as a help to diagnosis. The cells show mitoses and are very characteristic. Chylous ascites may occur. Secondary cancer of the liver is very common; the enlargement may be great, and such cases are not infrequently mistaken for primary cancer of the organ. Involvement of the lymph glands may give valuable indications. There may be early enlargement of a gland above the inner end of the left clavicle; later adjacent glands may become affected. This occurs also in uterine cancer.

A remarkable picture is presented when the cancer *sloughs* or becomes gangrenous; the vomitus has a foul-odor, often of a penetrating nature, to be perceived throughout the room. In cases in which the ulcer perforates the colon the vomiting may be faecal.

Course.—While usually chronic and lasting from a year to eighteen months, an acute course is by no means infrequent. Of 69 cases in which we could determine accurately the duration, 15 lasted under three months, 16 from three to six months, 14 from six to twelve months—a total of 45 under one year. Four cases lasted for two years or over. One patient lived for at least two years and a half.

Diagnosis.—Every effort should be made to recognize carcinoma before a tumor is present. Persistent gastric symptoms in an individual over forty require that malignant disease be excluded. Repeated studies of the gastric contents with comparison of the findings and the X-ray examination are the greatest aids. The X-ray picture is modified, the peristaltic waves are interfered with, anti-peristalsis and shadows varying in intensity with the degree of induration of the carcinoma may be seen. The constant presence of occult blood in the stools is important. In a doubtful case exploration should be advised without much delay if the findings are suspicious. There are cases in which a positive diagnosis can be reached in no other way.

In 115 of our 150 cases a tumor existed, and with this the recognition is rarely in doubt, but it is too late for removal. The chief difficulty is in cases with gastric symptoms or anæmia, or both, without the presence of tumor. In the one a chronic gastritis is suspected; in the other a primary anæmia. In chronic gastritis the long history, the absence of cachexia, the absence of lactic acid in the test meal, and the less striking blood changes are important points for consideration. The cases with grave anæmia without tumor offer the greatest difficulty. The blood-count is rarely so low as in pernicious anæmia. In only 8 of 59 cases with careful blood examination were the red cells below 2,000,000 per c. mm. The lower color index, as in secondary anæmia, the absence of megaloblasts, and a leucocytosis speak for cancer. With metastases in the bone marrow the blood picture may be that of pernicious anæmia (Harrington and Teacher).

From ulcer of the stomach malignant disease is, as a rule, readily recognized. The ulcus carcinomatosum usually presents a well-marked history of

ulcer for years. The greatest difficulty is offered when there is ulcer with tumor due to cicatricial contraction about the pylorus. In 3 such cases we mistook the mass for cancer, and even at operation it may (as in one of them) be impossible to say whether a neoplasm is present.

Treatment.—In early surgical treatment lies the only hope, but there is great difficulty in the diagnosis. Operated upon early, complete removal is sometimes possible. In a majority of cases the operation is only palliative. In suitable cases early exploration should be advised; the operation *per se* is sometimes beneficial and the patient is rarely the worse for it. W. J. Mayo reported 651 resections of the stomach in a period of twenty years. Of one series of 239 patients who recovered from the operation and were traced, 62 were alive five years or more afterwards.

The diet should consist of readily digested substances of all sorts. Many patients do best on milk alone. Washing out the stomach, which may be done with a soft tube without any risk, is particularly advantageous when there is obstruction at the pylorus, and is the most satisfactory means of combating vomiting and excessive fermentation. When the pain becomes severe, particularly if it disturbs the rest at night, morphia must be given. One-eighth of a grain (0.008 gm.), combined with bicarbonate of soda (gr. v, 0.3 gm.), bismuth (gr. v-x, 0.3-0.6 gm.), usually gives prompt relief, and the dose does not always require to be increased. Creosote (m j-ij, 0.06-0.12 c. c.) and one or two drops of carbolic acid in glycerine are useful. The bleeding is rarely amenable to treatment. In cases which are inoperable the use of radium or deep X-ray therapy is worthy of trial.

Other Forms of Tumor.—*Non-cancerous tumors* of the stomach rarely cause inconvenience. *Adenoma* occurs in several forms: *polypoid adenomata* are common and are often numerous, one to two hundred; the adenoma may form an area raised above the level of the mucosa; or there may be a rare form of Brunner's glands. *Adenoma* usually occurs in patients over 50 and gives features suggestive of chronic gastritis which are not distinctive. With *polyposis*, nausea and hæmorrhage are common. The X-ray picture is characteristic, showing a mottled area with barium trickling round the masses. H. B. Anderson described a case of multiple *cysts* in the walls of the stomach and small intestine. *Sarcomata* are rare. Douglas (1920) found 230 cases in a study of the literature. There are no definite clinical features different from carcinoma except the occurrence in younger patients. *Fibromata* and *lipomata* have been described. External polypoid tumors, myo- or fibro-sarcomata may grow from the peritoneal surface, usually the posterior, of which Sherran collected 18 cases.

Foreign bodies occasionally produce remarkable tumors of the stomach. The most extraordinary is the *hair tumor* which occurs in hysterical women who have been in the habit of eating their own hair. A specimen in the medical museum of McGill University is in two sections, which form an exact mold of the stomach. The tumors are large, very puzzling, and are usually mistaken for cancer. Of 7 cases operated upon, 6 recovered; in 9 cases the condition was found post mortem (Schulten).

VII. HYPERTROPHIC STENOSIS OF THE PYLORUS

In Adults.—Microscopically, the condition is found to be very largely hypertrophy of the muscularis and submucosa of the pylorus. The symptoms are those of dilatation of the stomach. Some of these cases may be congenital, as there have been instances reported in older children and adults. In some cases it may be due to marked pylorospasm.

Congenital.—This remarkable affection, first recognized by Beardsley of Connecticut, has been thoroughly studied by many authorities. There is marked thickening of the pylorus with resulting obstruction.

ETIOLOGY.—There are two possibilities, one that the cause is a congenital hypertrophy of the pylorus and the other that spasm is responsible. The latter is probably the cause in the majority of cases and is due to overaction of the vagus. The importance of spasm is suggested by the fact that the tumor may persist after the symptoms have disappeared. A large proportion of the cases occurs in first born children and about 80 per cent. in boys. The majority of the children are breast fed. There is marked thickening of the circular muscle fibres of the pylorus with resulting dilatation of the stomach.

SYMPTOMS.—These are rare in the first week of life and usually appear from the second to the fourth week. Vomiting of food and wasting are constantly present; the former begins, as a rule, during the second or third week, and in a few instances at birth; it occurs usually soon after nursing. It is often of the expulsive type; the vomitus often contains mucus, rarely blood. The wasting becomes extreme, there are marked constipation, acidosis not infrequently, great weakness, sometimes terminal diarrhœa, or a sudden fatal syncope.

PHYSICAL SIGNS.—These are distinctive—*visible peristalsis* and *palpable tumor*. The peristalsis is best seen after feeding, when the waves pass at intervals, in characteristic form, from left to right above the navel; two or three waves may be seen at once. The pyloric tumor may be felt as a firm, hard, freely movable body, to the right of the navel and a little above it, which varies in size and consistency, and through which gas may sometimes be felt to gurgle. The X-ray examination adds little. There are no sequels; if the child recovers the hypertrophy of the pylorus disappears.

DIAGNOSIS.—This offers little difficulty if peristalsis is observed. Ordinary vomiting has not a projectile character and mild grades of pyloric spasm do not cause peristalsis or the general features.

TREATMENT.—Medical treatment consists in feeding with breast or modified milk, 1-2 ounces every 2 or 3 hours. Dextrose solution (200 c. c., 4 per cent.) can be given by the bowel. Lavage of the stomach should be done twice a day. Atropine is useful in some cases, by its effect on spasm, in dosage carefully studied for each patient. Some suggest giving it hypodermically until the vomiting is controlled and then by mouth. The initial dose may be one drop of a 1-1000 solution, freshly prepared (Haas). There should not be delay in resorting to surgical measures if improvement does not occur. The division of the circular muscular layer (Rammstedt's operation) is a successful procedure (47 recoveries in 61 cases). The after care is impor-

tant. The child should be kept warm, given fluid by bowel and subcutaneously, and fed carefully with a gradual increase in the amount.

VIII. HÆMORRHAGE FROM THE STOMACH

(Hæmatemesis)

Etiology.—Hæmatemesis may result from many conditions, local or general. (a) In local disease: (1) cancer; (2) ulcer; (3) disease of the blood-vessels, such as miliary aneurisms and occasionally varicose veins; (4) acute congestion, as in gastritis, and possibly in vicarious hæmorrhage; (5) following operations in the abdomen, particularly when the omentum is wounded, erosions of the gastric mucosa may occur, from which hæmorrhage takes place. It is a very fatal complication after appendicitis and is usually associated with peritonitis.

(b) Passive congestion due to obstruction in the portal system. This may be (1) hepatic, as in cirrhosis of the liver, thrombosis of the portal vein, or pressure upon the portal vein by tumor, and secondarily in chronic disease of the heart and lungs. (2) Splenic. Gastric hæmorrhage is by no means uncommon with splenomegaly, and is explained by the intimate relations between the vasa brevia and the splenic circulation. 22

(c) Toxic: (1) In some specific fevers, as small-pox and yellow fever; (2) unknown poisons, as in acute yellow atrophy and purpura; (3) phosphorus.

(d) Trauma: (1) Mechanical injuries, as blows and wounds, and occasionally by the stomach-tube; (2) the result of severe corrosive poisons.

(e) Certain constitutional diseases: (1) Hæmophilia; (2) profound anæmias; (3) cholæmia.

(f) In certain nervous affections, particularly hysteria, and occasionally in general paresis and epilepsy.

(g) The blood may not come primarily from the stomach but from the nose or pharynx. In hæmoptysis some of the blood may find its way into the stomach. In bleeding from the œsophagus blood may trickle into the stomach, from which it is ejected. This occurs in the case of rupture of an aneurism and of œsophageal varices. A child may draw blood with the milk from the mother's breast and then vomit it.

(h) Gastrostaxis: Under this name Hale White described cases of hæmorrhage from the stomach in young girls without any evident lesion of the mucosa. They are often mistaken for ulcer. At operation the blood has been seen oozing from points in the mucosa. There may be no pain or any of the ordinary features of ulcer.

(i) Miscellaneous causes: Aneurism of the aorta or of its branches may rupture into the stomach. There are instances in which a patient has vomited blood once without any recurrence or without developing symptoms pointing to disease of the stomach. In new-born infants hæmatemesis may occur alone or in connection with bleeding from other mucous membranes.

In medical practice, hæmorrhage from the stomach occurs most frequently with cirrhosis of the liver and ulcer of the stomach or duodenum.

Morbid Anatomy.—When death has occurred from the hæmatemesis

there are signs of intense anæmia. The lesion is evident in cancer and in ulcer of the stomach. Fatal hæmorrhage may come from a small miliary aneurism communicating with the surface by a pinhole perforation, or the bleeding may be due to the rupture of a submucous vein and the erosion in the mucosa may be small and readily overlooked. It may require a careful and prolonged search to find such lesions. In the large group associated with portal obstruction, the mucosa is usually pale, smooth, and shows no trace of any lesion. In cirrhosis, fatal by hæmorrhage, one may sometimes search in vain for any local lesion and we must conclude that it is possible for even the most profuse bleeding to occur by diapedesis. The stomach may be distended with blood and yet the source of the hæmorrhage be not apparent. In such cases the œsophagus should be examined carefully. In toxic cases there are invariably hæmorrhages in the mucous membrane itself.

Symptoms.—In rare instances fatal syncope may occur without any vomiting. In a case of the kind, in which the woman fell over and died in a few minutes, the stomach contained between three and four pounds of blood. The sudden profuse bleedings rapidly lead to profound anæmia. When due to ulcer or cirrhosis the bleeding usually recurs for several days. Fatal hæmorrhage from the stomach is met with in ulcer, cirrhosis, enlargement of the spleen, and in instances in which an aneurism ruptures into the stomach or œsophagus. Gastric hæmorrhage may occur in splenic anæmia or leukæmia before the condition has aroused attention.

The vomited blood may be fluid or clotted; it is usually dark in color, but in the basin the outer part becomes red from the action of the air. The longer blood remains in the stomach the more altered it is when ejected.

The amount of blood lost is very variable, and in a day the patient may bring up three or four pounds, or even more. In a case under the care of George Ross, in Montreal, the patient lost during seven days ten pounds, by weight, of blood. The usual symptoms of anæmia develop rapidly, and there may be slight fever and subsequently œdema. Syncope, convulsions, and occasionally hemiplegia occur after very profuse hæmorrhage. Blindness may follow, the result of thrombosis of the retinal arteries or veins, or an acute degeneration of the ganglion cells of the retina.

Diagnosis.—In a majority of instances there is no question as to the origin of the blood. Occasionally it is difficult, particularly if the patient is not seen during the attack. Examination of the vomitus readily determines whether blood is present or not. The material vomited may be stained by wine, the juice of strawberries, raspberries, or cranberries, which give a color closely resembling that of fresh blood, while iron, bismuth and bile may produce the blackish color of altered blood. In such cases the microscope shows the shadowy outlines of the red blood cells, and spectroscopic and chemical tests may be applied.

Deception is sometimes practised by hysterical patients, who swallow and then vomit blood or colored liquids. With a little care such cases can usually be detected. The cases must be excluded in which the blood comes from the nose or pharynx, or in which infants swallow it with the milk.

There is not often difficulty in distinguishing between hæmoptysis and hæmatemesis, though coughing and vomiting are not infrequently combined, by a careful history and thorough study.

Prognosis.—Except in the case of rupture of an aneurism or of large veins, the impression is that hæmatemesis rarely proves fatal, but among 526 cases of severe hæmatemesis death followed in 67, 10.8 per cent. (Bulmer). In our experience death follows relatively more frequently in hepatic cirrhosis than in ulcer or cancer. In the chronic hæmorrhagic form of ulcer the bleeding may recur for years. The treatment of hæmatemesis is considered under gastric ulcer.

IX. NEUROSES OF THE STOMACH

(*Nervous Dyspepsia*)

Serious functional disturbances of the stomach may occur without any discoverable anatomical basis. The cases are most frequent in those who have either inherited a nervous constitution or who have gradually, through indiscretions, brought about a condition of nervous prostration. Not infrequently, the gastric symptoms stand so far in the foreground that the general neuropathic character of the patient quite escapes notice. Sometimes the gastric manifestations have a reflex origin depending on organic disturbances in other parts, such as the gall-bladder, appendix or colon.

In all disturbances of the digestive tract, attention must be given to the whole and not to one part only. The digestive tube is a complicated mechanism which requires perfect coördination for proper function. Disease of one part may disturb the working elsewhere as, for example, disease of the appendix may cause gastric symptoms. Great importance attaches to proper motor function and many disturbances are due to this being disturbed. Motility may be increased, slowed, reversed or stopped, and any of these may result in symptoms. Contraction of a segment causes inhibition of the segment distal to it and this is particularly important in special zones, e. g., the pylorus and duodenum. Irregularities and blocks may occur as in the heart, especially where one zone passes into another, e. g., at the pylorus and ileo-cæcal valve. The nervous control plays a large part and the importance of vagotonia must always be kept in mind. Keith divides the digestive tract into neuromuscular sections, each separated from the adjoining one by a sphincter which blocks the passage of waves of contraction. He compares these to the blocks on a railroad, in which if one is blocked, the others are also.

As this group of stomach disorders does not represent a disease or even a symptom-complex there is the greatest variety in the clinical picture, not only in the comparison of one patient with another but in the same patient from time to time. It may require careful study to estimate the various causal factors and the possibility of organic disease manifesting itself as functional gastric disturbance must not be forgotten.

Alvarez has drawn attention to the part played by reversed peristalsis in causing symptoms. For example, regurgitation may be due to a distended and over-active colon or irritation from a diseased appendix. Vomiting may be due to increased tone and activity in the jejunum for which an irritable colon may be responsible. Belching of gas may represent reversed peristalsis set up by some organic lesion. Nausea is due more often to intestinal lesions, e. g., in the colon with reversed peristalsis, than to disease of the cesophagus

and stomach. As to the cause of a coated tongue there is no proof that it is always due to gastric disease. It may be due to regurgitation, as particles of material from the colon may easily reach the tongue. The condition termed "biliousness" is often a result of reversed intestinal activity originating in the colon and when this is emptied relief is obtained.

Motor Disturbances.—(a) HYPERMOTILITY.—Common with duodenal ulcer, this is usually a secondary disturbance, but sometimes is primary so far as any other condition can be found. There are no characteristic symptoms but some patients are satisfied with small amounts of food and suffer from hunger and discomfort two or three hours later. This is relieved at once by taking food or liquid. If pyloric spasm is associated with hypermotility there may be attacks of considerable distress associated with acid regurgitation or vomiting. The diagnosis is made by the test meal study or by the X-ray examination.

(b) PERISTALTIC UNREST.—This is a common and distressing symptom. Shortly after eating, the peristaltic movements of the stomach are increased, and borborygmi and gurgling may be heard, even at a distance. The subjective sensations are most annoying, and it appears as if in the hyperæsthetic condition the patient felt normal peristalsis, just as in these states the usual beating of the heart may be perceptible to him. A further analogy is afforded by the fact that emotion increases this peristalsis. It may extend to the intestines, and on palpation the gurgling is marked. The cause is usually reversed peristalsis due sometimes to disease elsewhere, as in the colon.

(c) ERUCTATIONS.—Aërophagia.—In this condition severe attacks of noisy eructations, often following one another in rapid succession, occur. When violent they last for hours or days. At other times they occur in paroxysms, depending often upon mental excitement. They are most common in neurotic individuals. The expelled air has usually been swallowed. Contrary to the common belief it does not come from fermentation except when there is pyloric obstruction. Aërophagia is common in general nervous disturbance but also occurs with organic conditions, such as gall-bladder disease. The patient feels some gastric discomfort which he regards as due to distention with gas and makes an effort to bring it up. In doing this he swallows air and after a time succeeds in eructing this. The common symptom is a feeling of fullness; if there is actual distention this may press on the diaphragm and cause palpitation and thoracic discomfort. In neurotic patients spasm of the diaphragm may cause pseudo-distention with fullness of the abdomen and great distress. The condition may disappear as rapidly as it came, without belching. Nervous patients often insist that the stomach is distended with gas when there is no evidence of it. If there is any doubt after the physical examination the use of the stomach tube or X-ray will settle the question.

(d) NERVOUS VOMITING.—This may be due to nervous influences acting directly or indirectly upon the vomiting centres. The patients are, as a rule, women and the subject of more or less marked nervous manifestations. A special feature of this form is the absence of preliminary nausea and of the straining efforts of the ordinary act of vomiting. It is rather a regurgitation, and without visible effort and without gagging the mouth is filled with the contents of the stomach, which are then spat out. It comes on, as a rule,

after eating, but may occur at irregular intervals. In some cases the nutrition is not impaired, a feature which may give a clue to the true nature of the disease, as there may be no other hysterical manifestation. It may occur in children, but in many cases this recurring vomiting is associated with acidosis. Nervous vomiting may be a very serious condition. We have had at least two fatal cases. In some instances, after persisting for weeks or months at home, the patient gets well in a few days in hospital. In other instances the course is protracted, and the cases are among the most trying we are called upon to treat.

One type of vomiting is associated with certain diseases of the nervous system—particularly tabes—forming part of the gastric crises. There are cases of primary periodic vomiting usually regarded as a neurosis.

(e) RUMINATION; MERYCISMUS.—In this remarkable condition the patients regurgitate and chew the cud like ruminants. It occurs in neurasthenic or hysterical persons, epileptics, and idiots. In some patients it is hereditary. In one instance a governess taught it to two children. The habit may persist for years, and does not necessarily impair the health.

(f) CARDIOSPASM; PHRENOSPASM; ACHALASIA.—There is much difference of opinion as to the nature of this condition. Regarded as spasm of the cardia the term *cardiospasm* was given, but Chevalier Jackson states that the obstruction is not at the cardia but where the œsophagus passes through the diaphragm (phrenospasm). There is lack of evidence of cardiospasm as shown by the absence of hypertrophy which would be expected in long-standing cases. Hurst regards the condition as due to an absence of the normal relaxation of the cardiac sphincter when the peristaltic wave reaches it and gives the name *achalasia*. Possibly it may occur at either situation; essentially there is interference with the mechanism of swallowing. In some cases at autopsy degenerative changes have been found in Auerbach's plexus between the muscular coats of the cardiac sphincter. In consequence of the obstruction, dilatation of the œsophagus results with hypertrophy of the walls.

Etiology.—Various causes may operate. A neurosis, neuritis, reflex action from disease above or below the diaphragm and irritation of the œsophagus have been suggested. Vagotonia is marked in some patients. In many cases no definite cause can be found.

Pathology.—There is large dilatation of the œsophagus, spindle-shaped or widest at its lowest part. The walls are grayish-white and wrinkled. There may be erosions. The hiatus œsophageus is not stenotic.

Symptoms.—These come on gradually. There may be a sense of obstruction with discomfort followed by salivation and regurgitation of food, especially on taking the recumbent position. The regurgitation may occur at once or be delayed for hours. Patients often encourage vomiting. Actual pain is rare. Some part of the contents may pass into the stomach but some food always remains and may become foul. The patient loses weight but it is remarkable how good the general condition may be.

Diagnosis.—The presence of obstruction and dilatation of the œsophagus is easily recognized by the X-ray study. Malignant disease and stenosis should be excluded by the use of the œsophagoscope.

(g) PYLOROSPASM.—This may be due to some irritative lesion of the stomach (ulcer) or elsewhere (gall-bladder or appendix), or occurs as part of

a neurosis (especially with vagotonia). There may be hypersecretion and hypermotility with it, in which case there may be severe attacks of discomfort and pain. Usually there is pain of the "hunger type," coming on 2 or 3 hours after meals, relieved by emptying the stomach or giving food. The pain is often referred to the region of the pylorus which can sometimes be felt as a hard mass which relaxes at intervals. Sometimes atony with dilatation results. Intermittent stagnation and hyperacidity may occur. It may not be easy to distinguish organic stricture from spasm but the duodenal tube usually passes the latter. The effect of atropine in relaxing spasm may be of aid. The X-ray examination is of great assistance.

(h) ATONY.—This occurs in general diseases which cause disturbance of nutrition, in anæmia, sometimes following pyloric obstruction, occasionally after an acute infection, but most often when the general nervous system is disturbed, especially if there is visceroptosis. The main symptom is gastric discomfort with a feeling of fullness during and after meals, or it may be continuous. In consequence the amount of food taken is reduced. There may be feelings of weight and pressure, eructations, etc. Pain is not present and vomiting is rare. The study of the gastric contents shows delay in emptying and variable acidity findings, often low. The X-ray study removes any doubt.

(i) INSUFFICIENCY OR INCONTINENCE OF THE PYLORUS.—This condition may be recognized by the rapid passing of gas from the stomach into the bowel on attempts at inflation of the former, as well as by the presence of intestinal contents in the stomach. There are no distinctive clinical symptoms.

(j) INSUFFICIENCY OF THE CARDIA.—This condition is only recognized by the occurrence of eructations or in rumination.

Secretory Neuroses.—(a) HYPERACIDITY; HYPERCHLORHYDRIA.—The studies of Hawk and Rehfuess and their co-workers have altered materially our views as to hyperacidity. They have shown that grades of acidity which we thought abnormal are normal in certain healthy individuals. Each has his own figure of gastric acidity and no general standard can be given. It is a question what symptoms are due to hyperacidity. Other disturbances, as in the motor function and pylorospasm, have to be taken into account. Organic disease, especially ulcer and reflex causes lower in the digestive tract, should always be considered. Yet there are some symptoms apparently associated with hyperacidity especially in nervous individuals. They do not, as a rule, immediately follow the ingestion of food, but occur one to three hours later, at the height of digestion. There is a sense of weight and pressure, with burning in the epigastrium, commonly associated with acid eructations. If vomiting occurs, the pain is relieved. The patient is usually relatively well nourished, and the appetite is good, though the sufferer may be afraid to eat on account of the anticipated pain. There is commonly constipation. Hyperacidity as a rule means hypersecretion.

(b) HYPERSECRETION.—This occurs in two forms, (a) continuous and (b) paroxysmal or intermittent; the former is the more common. The common causes are ulcer, gastric or duodenal, reflex influences from other abdominal diseases, as in the gall-bladder or appendix, and general nervous disturbance. The symptoms are much like those of hyperacidity. In the continuous form gastric distress, burning sensations and acid eructations are common. As

the secretion continues when the stomach is empty the symptoms may occur during the night. Examination of the fasting stomach shows the presence of varying amounts of highly acid fluid with a high percentage of HCl. If pylorospasm exists there may be more or less gastric dilatation. In the paroxysmal form the excessive secretion may continue for hours or days. It occurs especially with tabes, hysteria and migraine. The attack begins with disturbed sensations in the stomach, often headache, and later vomiting of the very acid fluid.

(c) **HYPOSECRETION.**—It may be difficult to distinguish between hyposecretion and hypo-acidity and the two are probably combined as a rule. Lack of or decreased secretion occurs in many diseases; gastritis, acute and chronic, cancer and atony of the stomach, some cases of gall-bladder disease and appendicitis, pernicious anæmia, multiple sclerosis and in functional nervous disorders. The influence of emotion, excitement and fear is familiar as a temporary phenomenon; if the condition is permanent the effect on gastric secretion is the same. There are no characteristic symptoms and the patient may have many complaints, mostly of sensory disturbance. If the motility is good there may be no symptoms. The diagnosis depends largely on the study of the stomach contents; repeated tests should be done before a decision is made. The effort should then be made to decide if the conditions are secondary and if so what primary condition is responsible.

(d) **ACHYLIA GASTRICA.**—This term was given by Einhorn to the condition in which there is a complete absence of gastric secretion. This may occur with atrophy of the gastric mucosa but is sometimes an inborn error of secretion and may be familial. The clinical features are variable and some patients are free from symptoms. There may be loss of appetite, nausea, and discomfort for some time after meals. Vomiting is rare. Diarrhoea, which may be chronic, occurs not infrequently. The physical examination shows nothing distinctive and the diagnosis depends on the study of the stomach contents. If atony occurs the symptoms are aggravated. The lack of response to histamine hydrochloride (0.25 mg. subcutaneously) distinguishes true achylia.

Sensory Neuroses.—(a) **HYPERÆSTHESIA.**—In this condition the patients complain of fullness, pressure, weight, burning, and so forth, during digestion, just such symptoms as accompany a variety of organic diseases of the stomach, and yet in all other respects the gastric functions appear quite normal. Sometimes these distressing sensations are present even when the stomach is empty. These symptoms are usually associated with manifestations of hysteria and neurasthenia. The pain often follows particular articles of food. An hysterical patient may apparently suffer severe pain after taking the smallest amount of food of any sort, while anything prescribed as a medicine may be well borne. In severe cases the patient may be reduced to an extreme degree by starvation.

(b) **GASTRIC PAIN.**—Severe pains in the epigastrium, paroxysmal in character, occur (1) as a manifestation of a functional neurosis, independent of organic disease, and usually associated with other nervous symptoms (it is this form which is here described); (2) in chronic disease of the nervous system, the so-called gastric crises; and (3) in organic disease of the stomach, such as ulcer or cancer, and with disease of the appendix and gall-bladder.

The functional neurosis occurs chiefly in women, very commonly in con-

nection with disturbed menstrual function or pronounced nervous symptoms. The affection may set in as early as puberty, but it is more common at the menopause. Anæmic, constipated women who have worries and anxieties are most prone to the affection but attacks sometimes occur in robust men. More often it is only one feature in general neurasthenia or a manifestation of that form of nervous dyspepsia in which there is hypersecretion.

The symptoms are very characteristic; the patient is suddenly seized with severe pains in the epigastrium, which pass toward the back and around the lower ribs. The attack is usually independent of the taking of food, and may recur at definite intervals. Vomiting is rare; more commonly the taking of food relieves the pain. To this, however, there are striking exceptions. Pressure upon the epigastrium commonly gives relief, but deep pressure may be painful. Stress has been laid upon the occurrence of painful points, but they are so common in neurasthenia that little importance can be attributed to them.

The diagnosis offers many difficulties. Organic disease of the stomach or of the nervous system, particularly the gastric crises of tabes, must be excluded. Disease elsewhere, such as in the gall-bladder or appendix, may be the etiological factor and search should be made for such lesions. The prolonged intervals between the attacks and their independence of diet are important features; but in many instances it is less the local than the general symptoms which enable us to make the diagnosis. In gall-stone colic jaundice is frequently absent, and in any long-standing case of gastralgia the question of cholelithiasis should be considered. Such a case may be treated for months as one of nervous dyspepsia until a more severe attack is followed by jaundice.

(c) ANOMALIES OF GASTRIC SENSATION; BULIMIA.—Abnormally excessive hunger may come in paroxysmal attacks, which cause the patient to commit extraordinary excesses in eating. This condition may occur in diabetes mellitus and sometimes in gastric disorders, particularly those associated with supersecretion. It is more commonly seen in hysteria and in the psychoses. It may occur in cerebral tumors, in Graves' disease, and in epilepsy.

The attacks often begin suddenly at night, the patient waking with a feeling of faintness and pain, and an uncontrollable desire for food. Sometimes such attacks occur immediately after a large meal. The attack may be relieved by a small amount of food, while at other times enormous quantities may be taken. In obstinate cases gastritis, atony, and dilatation frequently result from overfilling the stomach.

HUNGER.—There may be a variety of disturbing sensations connected with hunger, especially in nervous patients. The possibility of hypoglycæmia being responsible should be considered. Some have a sudden sensation of extreme weakness with anxiety and sometimes dizziness and sweating; syncope may follow. This condition may be part of a neurosis but ulcer should always be excluded. In another form the patient may be very hungry when beginning a meal but after taking a small amount of food there is a feeling of satiety and no more food is taken. This is practically always in nervous patients.

AKORIA.—An absence of the sense of satiety.—This condition is commonly associated with bulimia and polyphagia, but not always. The patient always

feels "empty." There are usually other well-marked manifestations of hysteria or neurasthenia.

PAROREXIA.—This term is applied to the condition in which the patient has a craving for very acid foods, and in hook-worm infection for a wide variety of substances, such as earth, string, cloth, etc.

ANOREXIA NERVOSA.—This condition, which is a manifestation of a neurotic temperament, is discussed under the general heading of Hysteria.

Nervous Dyspepsia.—This is not a satisfactory term, but it is difficult to find a better one to designate the condition in a large group of patients who complain of gastric disturbance, without any organic disease of the stomach or elsewhere in the abdomen, apparently secondary to neurasthenia and allied states. There is general fatigue, psychical, emotional and physical. The digestive symptoms are characteristic only in their irregularity and uncertainty. Discomfort is a common complaint, usually worse after meals, but varying in occurrence and severity. It has no special relation to any particular food unless the patient gets the notion that some particular food is responsible and expects trouble. Then it usually comes. In consequence one article of food after another is given up and the nutrition may suffer. Distention and flatulency are common, often associated with air swallowing. Constipation is usual and mucous colitis common. Loss of weight may result from insufficient food. There are no special physical findings in the abdomen except general tenderness. There may be atony of the stomach. The stomach contents may be normal but usually show some change, perhaps most often hyposecretion. The diagnosis should only be made after organic disease is excluded. The possibility of disease of the gall-bladder or appendix should be particularly considered. Evidences of the general condition are usually marked. The gastric symptoms reflect the general state; with worry or depression they are worse while with some new interest for a time they are less or disappear temporarily.

Treatment of Neuroses of the Stomach.—The most important part is often that directed toward the improvement of the general physical and mental condition of the patient. The possibility that the symptoms may be of reflex origin should be borne in mind; eye-strain, cholelithiasis, or chronic appendicitis should be considered. A large proportion of cases of nervous dyspepsia are dependent upon mental and physical exhaustion or worry, and a vacation or a change of scene will often accomplish what treatment at home has failed to do. The manner of life should be investigated and a proper amount of exercise in the open air and systematic hydrotherapy insisted upon. This in some cases is sufficient to cause the symptoms to disappear. Many cases with marked neurasthenic or hysterical symptoms do well on the Weir Mitchell treatment.

In "cardiospasm" the earlier that treatment is begun the better the outlook. The diet should be simple, and atropine may be given. Sometimes the passage of the oesophagoscope is sufficient, but usually the use of Plummer's water bag or a mercury tube is necessary. This may only require to be used once or in more obstinate cases more frequently. In chronic cases with oesophagitis, the patient should try to empty the oesophagus soon after every meal. Operation has been done, the cardiac sphincter being divided longitudinally.

The treatment in *atony* of the stomach should be similar to that adopted in moderate dilatation—the administration of small quantities of food at frequent intervals; the limitation of fluids, which should be taken in small amounts at a time; lavage. Strychnine in full doses may be of value. A proper abdominal support and sleeping with the foot of the bed elevated are useful aids.

In the distressing cases of *hyperacidity*, in addition to the treatment of the general neurotic condition, alkalies must be employed as magnesia, calcium carbonate or bicarbonate of soda. These should be given in large doses and at the *height of digestion*. In *hyperacidity* and *hypersecretion* the use of atropine frequently gives relief. It should be given before food and in small doses at first, beginning with 1/150 grain (0.0004 gm.) and gradually increasing. The combination of bromide and belladonna is sometimes useful. The diet should be mainly of proteins and fats with carbohydrate in small amounts. Meat, chicken, fish, eggs, cheese, milk and cream, and butter form the bulk of the diet. Bread is allowed in small amounts, stale or as toast. Condiments and alcohol should be avoided. Special emphasis should be placed on the need of thorough mastication. Half an ounce of olive oil is useful before meals. The bowels should be kept freely open, for which mineral oil is useful. The diet should be gradually increased with sparing addition of starches. The patient should carry alkali with him to take at the first sign of discomfort.

In *supersecretion* the use of the stomach-tube is of the greatest value. In the periodical form it should be used as soon as the attack begins. The stomach may be washed with alkaline solutions or a solution of nitrate of silver (1 to 1,000). Where this is impracticable the taking of albuminous food may give relief. Alkalies in large doses are indicated. In *continued supersecretion* there are usually atony and dilatation. The diet here should be much as in *superacidity*, but in smaller quantities at frequent intervals. Lavage with alkaline solutions is of great value. To relieve pain alkalies should be given freely at the height of digestion. Atropine is usually of value.

In *subacidity* a carefully regulated, easily digestible mixed diet, not too rich in protein, is advisable. Prolonged mastication is important. Bitter tonics before meals are sometimes of value. Dilute hydrochloric acid should be given freely and the dosage and best method of administration determined for each patient. Thirty to 60 drops may be added to a glass of water and taken during the latter part of the meal and for half an hour afterwards or doses of 30 drops taken 15 and 30 minutes after meals. In *achylia gastrica* the use of predigested foods and of hydrochloric acid in full doses may be of assistance.

In marked *hyperaesthesia*, the treatment of the general condition is especially important. Nitrate of silver in doses of gr. $\frac{1}{4}$ - $\frac{1}{2}$ (0.016 to 0.032 gm.), may be given for a short time. Abdominal compresses are useful.

For pain large doses of alkalies should be given, of which the light magnesia and bicarbonate of soda are the best. A teaspoonful of either or of a mixture of equal parts may be given after food and when required. A combination of potassium bromide (gr. xv, 1 gm.) with codeine (gr. $\frac{1}{3}$, 0.02 gm.) or atropine (gr. $\frac{1}{100}$, 0.00065 gm.) is sometimes useful. Chloroform in small doses or Hoffman's anodyne will sometimes allay the severe pains. The

general condition should receive careful attention, and in many cases the attacks recur until the health is restored by change of air with the prolonged use of arsenic. If there is anæmia iron may be given freely.

There are forms of nervous dyspepsia occurring in women who are often well nourished and with a good color, yet who suffer—particularly at night—with flatulency and abdominal distress. The sleep may be quiet for two or three hours, after which they are aroused with painful sensations in the abdomen and eructations. The appetite and digestion may appear to be normal but constipation is usually present. In many of those patients the condition seems rather intestinal and the distress is due to the accumulation of gas and reversed peristalsis. The fats, starches, and sugars should be restricted. Some obtain relief from irrigation of the colon at bedtime. Bromide and small doses of pheno-barbital are of value. The state of the nervous system should be carefully studied.

In all forms of gastric neurosis special care should be taken to prevent constipation.

G. DISEASES OF THE INTESTINES

I. DISEASES OF THE INTESTINES ASSOCIATED WITH DIARRHŒA

ENTERITIS; DIARRHŒA

Diarrhœa results from too rapid passage of the contents through the intestine, resulting in fluid stools. Care should be taken not to use the term for the passage of frequent solid stools, which may be due to constipation, or, if the word diarrhœa is used in a restricted sense, for the frequent stools of dysentery.

In the classification of acute enteritis the anatomical divisions of the bowel have been too closely followed, and a duodenitis, jejunitis, ileitis, typhlitis, colitis, and proctitis have been recognized; whereas in a majority of cases the entire intestinal tract, to a greater or lesser extent, is involved, sometimes the small most intensely, sometimes the large bowel; but during life it may be quite impossible to say which portion is specially affected.

Etiology.—The causes may be either *primary* or *secondary*. Among the causes of *primary enteritis* are: (a) *Improper food*, one of the most frequent, especially in children, in whom it follows overeating or the ingestion of unripe fruit. In some individuals special articles of diet produce a slight diarrhœa, which may not be due to a catarrh of the mucosa, but to increased peristalsis induced by the offending material. (b) *Infection.* The cases of food poisoning are fairly common in mild forms; possibly some are instances of colon bacillus infection. Infection from the mouth may be responsible in some cases. There may be chronic or intermittent diarrhœa due to fermentative or putrefactive conditions in the bowel. (c) *Various toxic substances.* Many toxins, such as those produced in the decomposition of milk and articles of food, excite the most intense enteritis. Certain inorganic substances, as arsenic and mercury, act in the same way. (d) *Gastrogenous*

diarrhœa. This is secondary to the absence of free hydrochloric acid in the stomach. There are three to six stools a day, usually without pain. The stools are loose and unformed, paler than normal and contain no mucus or blood. (e) *Changes in the weather*. A fall in the temperature of from twenty to thirty degrees, particularly in the spring or autumn, may induce—how, it is difficult to say—an acute diarrhœa. On the other hand, the diarrhœal diseases of children are associated in a very special way with the excessive heat of the summer months. (f) *Changes in the intestinal secretions*. We know too little about the *succus entericus* to be able to speak of influences induced by change in its quantity or quality. It has long been held that an increase in the amount of bile poured into the bowel might excite a diarrhœa. Possibly there are conditions in which an excessive amount of bile is poured into the intestine, increasing peristalsis, and hurrying on the contents; but a scanty secretion, by favoring fermentative processes, much more commonly causes an intestinal catarrh. Absence of the pancreatic secretion from the intestine is associated in certain cases with a fatty diarrhœa. (g) *Nervous influences*. Mental states may profoundly affect the intestinal canal. These probably act through the autonomic system. As a result of stimulation of the vagus, peristalsis is increased. These influences should not properly be considered under catarrhal processes, as they result from disturbed peristalsis and are usually described as *nervous diarrhœa*. In children it frequently follows fright. It is common in adults as a result of emotional disturbances. Canstatt mentions a surgeon who always, before an important operation, had watery diarrhœa. In hysterical women it is an occasional occurrence, due to excitement, or a chronic protracted diarrhœa, which may last for months or years.

Among the *secondary* causes may be mentioned: (a) *Infectious diseases*. Cholera, typhoid fever, pyæmia, septicæmia, and tuberculosis may have an associated enteritis. In typhoid fever the ulceration is in part responsible but in cholera it is probably a direct influence of the bacilli or of the toxic materials produced by them. (b) *The extension of inflammatory processes from adjacent parts*. Thus, in *peritonitis*, catarrhal swelling and increased secretion are always present in the mucosa. In cases of *invagination*, *hernia*, *tuberculosis*, or *cancerous ulceration* catarrhal processes are common. (c) *Circulatory disturbances* cause a catarrhal enteritis, usually of a very chronic character. This is common in diseases of the *liver*, such as *cirrhosis*, and in chronic affections of the *heart and lungs*—all conditions, in fact, which produce engorgement of the terminal branches of the portal vessels. (d) In *cachectic conditions* in cancer, profound anæmia, Addison's diseases, and nephritis enteritis may occur as a terminal event.

Morbid Anatomy.—It is rare to see the mucous membrane injected; more commonly it is pale and covered with mucus. In the upper part of the small intestine the tips of the valvulæ conniventes may be deeply injected. The entire mucosa may be softened and infiltrated, the lining epithelium swollen, or even shed, and appearing as large flakes among the intestinal contents. This is, no doubt, a post-mortem change. The lymph follicles are almost always swollen, particularly in children. The Peyer's patches may be prominent and the solitary follicles stand out with distinctness and present erosions, the so-called follicular ulcers. This may be a striking feature in all

forms of catarrhal enteritis in children, irrespective of the intensity of the diarrhoea. When the process is more chronic the mucosa is firmer, in some instances thickened, in others thinned, and the villi and follicles present a slaty pigmentation.

Symptoms.—Acute and chronic forms may be recognized. The important symptom of both is *diarrhoea*, which, in the majority of instances, is the main indication. *Diarrhoea* is not invariably caused by, or associated with, enteritis, as it may be produced by nervous and other influences. It is probable that catarrh of the jejunum may exist without any diarrhoea; indeed, it is common to find post mortem a catarrhal state of the small bowel in persons who have not had diarrhoea during life. The stools vary extremely in character. The color depends upon the amount of bile which they contain, and they may be of a dark or blackish brown, or of a light yellow, or even of a grayish-white tint. The consistence is usually thin and watery, but in some instances the stools are pultaceous like thin gruel. Portions of undigested food can often be seen (*lienteric diarrhoea*), and flakes of yellowish-brown mucus. Microscopically there are innumerable micro-organisms, epithelium and mucous cells, crystals of phosphate of lime, oxalate of lime, and occasionally cholesterin and Charcot's crystals. In *enteritis* there is unchanged bile, the stools may be green, cellulose is not digested and the mucus is intimately mixed with the stool. In *colitis* the stool is usually browner, cellulose is largely digested and the mucus is on the outside of the faeces and may be in large masses.

Pain in the abdomen is usually present in *acute* enteritis, particularly when due to food. It is of a *colicky* character, and when the colon is involved there may be tenesmus. *More or less tympanites* exists, and there are gurgling noises due to the rapid passage of fluid and gas from one part to another. In very acute attacks there may be vomiting usually due to an associated gastritis. Fever is not, as a rule, present, but there may be a slight elevation. The appetite is lost, there is intense thirst, and the tongue is dry and coated. In very acute cases, when the quantity of fluid lost is great and the pain excessive, there may be collapse symptoms. The number of stools varies from four or five to twenty or more in the day. The attack lasts for two or three days, or may be prolonged for a week or ten days.

Chronic diarrhoea may follow the acute form, or come on gradually as an independent affection or as a sequence of obstruction in the portal circulation. It may be with or without colic. The dejections vary; when the small bowel is chiefly involved the diarrhoea is of a *lienteric* character, and when the colon is affected the stools are thin and mixed with much mucus. The most common causes are (1) *gastrogenous*, (2) *tuberculous enteritis*, (3) *pancreatic disease*, (4) *fatty or chylous diarrhoea* with disease of the absorption system, and (5) *emotional*. A special form of mucous diarrhoea will be subsequently described. The general nutrition in these chronic cases is greatly disturbed; there may be much loss of flesh and great pallor. The patients are inclined to suffer from depression or hypochondriasis.

In some individuals there is the passage of a loose stool after meals, probably due to an active gastro-colic reflex. This may occur only after breakfast or after every meal. Some of the patients in addition pass a loose stool at once on rising in the morning. There is rarely any abdominal dis-

comfort but there may be a feeling of weakness, slight or marked, after each movement. Disturbance in the sympathetic system is usually responsible.

Carbohydrate Indigestion.—This may involve both the stomach and bowels. The main symptom is distention from gas. The stools are acid and contain much undigested starch. If there is much fermentation the stools in addition are mushy and contain bubbles of gas. The result of a protein-fat diet is an important point in the diagnosis.

Diagnosis.—In acute cases there is rarely much doubt, but dysentery may be confused. The distinction is sometimes difficult but tenesmus with blood and mucus in the stools is fairly characteristic of dysentery. In acute cases cultures from the bowel or stools are important. In subacute or chronic attacks care should be taken to be sure that the contents pass rapidly through the intestine by giving charcoal or some coloring matter. An X-ray study answers the question very readily. There may be frequent watery stools due to the presence of scybala in the colon. When the large intestine is at fault there may be no pain, as in the cases associated with tuberculosis and nephritis. When present, the pains are intense, and, if the lower portion of the bowel is involved, there may be tenesmus. With the sigmoidoscope the changes in the mucous membrane may be seen. In older patients a persistent or recurring diarrhoea should suggest the need of excluding malignant disease in which the sigmoidoscope and X-ray study are important.

Duodenitis is usually associated with acute gastritis and, if the process extends into the bile-duct, with jaundice. The study of the duodenal contents aids in the diagnosis.

Celiac Disease.—As the "celiac affection" Gee described an intestinal disorder, most common in children between the ages of one and five, characterized by the occurrence of pale, loose stools, not unlike gruel or oatmeal porridge. They are bulky, not watery, yeasty, frothy, and extremely offensive. There is disturbance in the digestion of fats and carbohydrates. There is no evidence of defective fat-splitting, of pancreatic disease or of enteritis. The affection has received various names, such as *diarrhoea alba* or *diarrhoea chylosa*. It is not associated with tuberculosis. It begins insidiously and there are progressive wasting, weakness, and pallor. The belly becomes doughy and inelastic with marked distention. There is often flatulency. Fever is usually absent. The diagnosis from tuberculous peritonitis may be difficult; the character of the stools is important. The duration is usually prolonged but recovery generally results. In treatment, the diet should contain a minimum of fat and carbohydrate. At first buttermilk and orange juice may be given with a gradual addition of protein foods, such as junket, gelatine and white of egg. Carbohydrate is added very carefully. An effort to give vitamins as freely as possible should be made. The giving of bile salts (gr. ii-iv, 0.12-0.24 gm.) is helpful in some cases. Ultra-violet radiation is useful.

Sprue or Psilosis.—It is difficult to decide where this disease should be placed. It occurs especially in the tropics, but is not infrequent in the United States, a point which Wood has emphasized. Ashford has worked extensively in the study of the disease in Porto Rico. He regards it as due to the combination of several factors causing glandular insufficiency to which are added the organism *Monilia psilosis*. Among the contributing causes to the glandular insufficiency are poor hygiene, frequent pregnancies, an ill-

balanced and badly prepared diet, and various wasting diseases. The preliminary symptoms are asthenia, dyspepsia, anorexia, constipation sometimes alternating with diarrhœa, reduction in the size of the liver, nervousness and depression, pallor and pigmentation of the skin. Later the more marked features are added. Disturbance of calcium metabolism has been suggested and also vitamin deficiency.

The chief features are: (1) Diarrhœa. The stools are very large, acid, light in color and contain a large amount of fat. It is a fatty diarrhœa, without pain or tenesmus, and the stools are like those of pancreatic insufficiency. The stools are usually passed between midnight and 10 A. M. The loss of fat varies from 30 to 50 per cent. There is marked nitrogen loss in the stools. (2) Tongue. This may be inflamed and show eroded patches or superficial cracks. (3) Anæmia. The color index may be high and the picture resemble that of pernicious anæmia. (4) The disease is chronic and remissions are common. There may be marked emaciation. There is often absence of free hydrochloric acid in the stomach contents. The diagnosis from pellagra has given difficulty but a study of the stools should prevent this.

In treatment, absolute rest in bed, a diet of finely chopped beef, cooked lightly and given four times a day, and at least four pints of hot water, have been found useful. Others advise a strict milk diet. Strawberries have a marked effect in some cases. Good results are reported from a combination of calcium lactate gr. x-xv (0.6-1 gm.) and parathyroid hormone. The giving of pancreatic ferments and the use of autogenous streptococcus vaccine should be tried. Liver extract should be given as in pernicious anæmia.

Hill Diarrhœa.—This occurs at high elevations, particularly in India, and comes on soon after arrival. The cause is obscure. Loose pale stools are passed in the morning. There is much flatulency. Treatment is not satisfactory and removal to a lower altitude may be necessary.

DIPHTHEROID OR CROUPOUS ENTERITIS

A croupous or diphtheroid inflammation of the mucosa of the small and large intestines occurs (a) most frequently as a secondary process in the infectious diseases—pneumonia, septicopyæmia and typhoid fever; (b) as a terminal process in many chronic affections, such as nephritis or cancer; and (c) as an effect of certain poisons—mercury, lead, and arsenic.

There are three anatomical pictures. (1) The mucosa presents on the top of the folds a thin grayish-yellow diphtheroid exudate situated upon a deeply congested base. In some cases all grades may be seen between the thinnest film of superficial necrosis and involvement of the entire thickness of the mucosa. In the colon similar transversely arranged areas of necrosis are seen situated upon hyperæmic patches, and it may be extensive and involve a large portion of the membranes. There may be most extensive inflammation without any involvement of the solitary follicles of the large or small bowel. (2) The membrane has rather a croupous character. It is grayish-white in color, more flake-like and extensive, limited, perhaps, to the cæcum or to a portion of the colon; thus, in pneumonia this flaky adherent false membrane may be found forming patches 1 to 2 cm. in diameter, not unlike rupia crusts. (3) The affection is really a follicular enteritis, involving the solitary glands, which are swollen and capped with an area of diphtheroid necrosis or are in a state of suppuration. Follicular ulcers are common in this form.

The disease may run its course without any symptoms, and the condition is unexpectedly met with post mortem. In other instances there are diarrhoea and pain, but not often tenesmus or the passage of blood-stained mucus. In the toxic cases the intestinal symptoms may be marked, but in the terminal colitis of the fevers and of chronic affections the symptoms are often trifling.

PHLEGMONOUS ENTERITIS

As an independent affection this is excessively rare, even less frequent than its counterpart in the stomach. It is seen occasionally in connection with intussusception, strangulated hernia, and chronic obstruction. Apart from these conditions it occurs most frequently in the duodenum, and leads to suppuration in the submucosa and abscess formation. Except when associated with hernia or intussusception the affection can not be diagnosed. The symptoms usually resemble those of peritonitis.

ULCERATIVE ENTERITIS

In addition to the specific ulcers of tuberculosis, syphilis, and typhoid fever, the following forms of ulceration occur in the bowels:

Follicular Ulceration.—This is very common in the diarrhoeal diseases of children, and also in the secondary or terminal inflammations in many fevers and constitutional disorders. The ulcers are small, punched out, with sharply cut edges, and are usually limited to the follicles. With this form may be placed the catarrhal ulcers of some writers.

Stercoral ulcers occur in long-standing cases of constipation. In some cases the sacculi of the colon become filled with rounded small scybala, some of which produce distinct ulcers in the mucous membrane. The faecal masses many have lime salts deposited in them, and thus form enteroliths.

Simple Ulcerative Colitis.—Apart from dysentery (bacillary, amœbic or terminal) there is a variety of ulcerative colitis, sometimes of great severity, not uncommon in England and the United States. It is a disease of adults, of unknown origin and the sexes are equally affected. Some patients have had previous bowel trouble; sometimes there have been intermittent attacks of diarrhoea and constipation. Post mortem, the colon is dilated, often without hypertrophied walls; the ulceration, as a rule, limited to it and very extensive, the ulcers ranging in size from a pin's head to large areas, with infiltrated, rarely undermined, edges. The dysentery bacillus is not present; various organisms are found but no one organism has any definite proved relation to the disease. When established, the main features are:

(a) Diarrhoea: The motions are very frequent in the day, up to 20 or 30, usually small, bile-stained, with mucus, pus, and blood, sometimes mixed with the motion or separate. There may be clotted lumps of blood, or the blood is uniformly mixed, and the motions look like anchovy sauce. The pain, while severe, is usually diffuse, abdominal, and colicky, and, not frequently in the rectum. Many of the motions pass without pain.

(b) Fever occurs in the majority of the cases, though severe forms may be free throughout.

(c) Wasting, debility, and progressive anæmia.

(d) With the sigmoidoscope the mucous membrane is seen to be red and cedematous. Later the cedema subsides and ulceration appears.

In diagnosis it is important to exclude dysentery and malignant disease.

The disease may run a very acute course, but most frequently it is chronic, lasting from eight weeks to three or four months. Transient improvement may follow, and a relapse. Death results usually from exhaustion, occasionally from hæmorrhage, and in a few instances from perforation.

Ulceration from External Perforation.—This may result from the erosion of new growths or, more commonly, from localized peritonitis with abscess formation and perforation of the bowel. This is met with most frequently in tuberculous peritonitis, but it may occur in the abscess which follows perforation of the appendix or suppurative or gangrenous pancreatitis. Fatal hæmorrhage may result from the perforation.

Cancerous Ulcers.—In very rare instances of multiple cancer or sarcoma the submucous nodules break down and ulcerate.

Solitary Ulcer.—Occasionally a solitary ulcer in the small bowel, cæcum or colon may lead to perforation. The cause is usually obscure; possibly thrombosis may be responsible. With obstruction in the lower colon causing stasis, there may be ulceration in the cæcum or ascending colon.

Diagnosis of Intestinal Ulcers.—As a rule, diarrhœa is present in all cases, but exceptionally there may be extensive ulceration, particularly in the small bowel, without diarrhœa. Very limited ulceration in the colon may be associated with frequent stools. The character of the dejections is of great importance. Pus, shreds of tissue, and blood are the most valuable indications. Pus occurs most frequently with ulcers in the large intestine, but when the bowel alone is involved the amount is rarely great, and the passage of any quantity of pure pus is an indication that it has come from without, most commonly from the rupture of an abscess. Pus may be present in cancer of the bowel or may be due to local disease in the rectum. A purulent mucus may be present in the stools in cases of ulcer, but it has not the same diagnostic value. The swollen, sago-like masses of mucus which are believed by some to indicate follicular ulceration are found also in mucous colitis. Hæmorrhage is an important and valuable sign of ulcer in the bowel, particularly if profuse. It occurs under so many conditions that taken alone it may not be specially significant, but with other coexisting circumstances it may be the most important indication of all.

Fragments of tissue are occasionally found in the stools in ulcer, particularly in the extensive and rapid sloughing in dysenteric processes. Definite portions of mucosa, shreds of connective tissue, and even bits of the muscular coat may be found. Pain occurs in many cases, either of a diffuse, colicky character, or sometimes, in the ulcer of the colon, very limited and well defined. Examination by means of tubes should always be done, as by them ulcers in the lower bowel may be viewed directly.

Perforation is an accident liable to happen when the ulcer extends deeply. In the small bowel it leads to a localized or general peritonitis. In the large intestine, a fatal peritonitis may result, or, if perforation takes place in the posterior wall of the ascending or descending colon, the production of a large abscess cavity in the retro-peritoneum.

Treatment of the Previous Conditions

Acute Diarrhœa.—The patient should be in bed and in acute cases no food should be allowed for twenty-four hours. If there is vomiting the stomach should be washed with an alkaline solution. If the attack has followed the eating of infected or indigestible food, castor oil or calomel is advisable, but is not necessary if the patient has been freely purged. If the pain is severe, 20 drops (1.3 c. c.) of laudanum and 5j (4 c. c.) of spirit of chloroform may be given, or, if the colic is very intense, a hypodermic of a quarter of a grain (0.016 gm.) of morphia. It is not well to check the diarrhœa unless it is profuse, as it usually stops spontaneously within forty-eight hours. If persistent, the aromatic chalk powder or large doses of bismuth (30 to 40 grains, 2 gm.) may be given. A small enema of starch (2 ounces, 60 c. c.), with 20 drops (1.3 c. c.) of laudanum, every six hours, is a valuable remedy. The diet should be increased very gradually during convalescence.

In the intense forms of choleraic diarrhœa in adults associated with constant vomiting and frequent stools the patient should be given a hypodermic of a quarter of a grain (0.016 gm.) of morphia, which should be repeated in an hour if the pains return or the purging persists. This gives prompt relief, and is often the only medicine needed. The patient should be stimulated, and, when the vomiting is allayed, given small quantities of milk and lime water.

Chronic diarrhœa, including chronic catarrh and ulcerative enteritis. An etiological diagnosis is usually essential for proper treatment. So much in treatment depends upon the careful examination of the stools—as to the amount of mucus, the presence of pus, the occurrence of parasites, and, above all, the state of digestion of the food—that the practitioner should pay special attention to them. Many patients simply require rest in bed and a restricted diet. Chronic diarrhœa of many months' or even of several years' duration may be sometimes cured by strict confinement to bed and a diet of boiled milk and albumen water. The patient should wear a warm abdominal binder and avoid chilling. A very simple diet should be taken. The use of finely powdered charcoal or kaolin in full doses is often helpful.

The *gastrogenous diarrhœa* may be promptly relieved by giving dilute hydrochloric acid in full doses. Calcium lactate (gr. xv, 1 gm.) and pancreatin are also useful.

In that form in which immediately after eating there is a tendency to loose evacuations it may be that some one article of diet is at fault. The patient should rest for an hour or more after meals. Sometimes this alone is sufficient to prevent the diarrhœa. Arsenic in moderate doses taken at the end of the meal is sometimes helpful. In cases in which this form is due to nervous disturbances attention should be given to their correction. The combination of bromide and belladonna is often helpful. In those forms which depend upon abnormal conditions in the small intestine, bismuth is indicated. It must be given in large doses— from half a dram to a dram (2 to 4 gm.). Salol and the salicylate of bismuth may be tried.

In the form due to *carbohydrate indigestion*, the carbohydrate should be greatly reduced or a protein-fat diet given. If the diarrhœa lessens, vegetables with a low carbohydrate content (see page 442) should be added gradually. Pancreatic extract is often useful. In diarrhœa with putrefaction a

diet of milk and its products with vegetables should be given. Meat and eggs should not be eaten. Acidophilus bacilli may be given alone or in special prepared milk.

An extremely obstinate and intractable form is the diarrhœa of hysterical and nervous women. A systematic rest cure will be found most advantageous with milk only for a time. The condition seems to be associated in some cases with increased peristalsis, and in such the bromides may do good, or preparations of opium may be necessary. There are instances which prove most obstinate and resist all treatment, and the patient may be greatly reduced. A change of air and surroundings may do more than drugs.

In a large group the mischief is seated in the colon and is due to ulceration. Medicines by the mouth are of little value but tincture of iodine, 10 to 20 drops, is sometimes of value and belladonna may be given if there is spasm. The stools should be carefully watched and a diet arranged which shall leave the smallest possible residue. Boiled or peptonized milk may be given. Sometimes a diet rich in vitamins is very useful in ulcerative colitis. Meat is, as a rule, badly borne in these cases. The diarrhœa is best treated by enemata. The starch and laudanum enema may be used for severe pain, but when ulceration is present it is better to use astringent injections. From 1 to 2 pints of nitrate of silver solution (1-5000) may be used. Neutral acriflavin (1-4000) in aqueous or saline solution (500-1000 c. c.) may be used twice a day and retained for fifteen minutes. The strength or frequency may be reduced if much mucus appears in the stools. In giving large injections the patient should be in the dorsal position, with the hips elevated, and it is best to allow the injection to flow in gradually from a siphon bag. In this way the entire colon can be irrigated and the patient can retain the injection for some time. The silver injections may be very painful, but they are invaluable in all forms of ulcerative colitis. Boracic acid, sulphate of copper, sulphate of zinc, and salicylic acid may be used in 1 per cent. solutions. Any ulcers which can be reached should be treated by local applications, of which the silver salts are particularly useful. In obstinate cases appendicostomy or cæcostomy should be done and the bowel irrigated through the opening, or an artificial anus made to give rest to the colon.

II. DIARRHOEAL DISEASES IN CHILDREN

Children are particularly susceptible to disorders of the alimentary tract. Although several forms are recognized, they so often merge the one into the other that a sharp differentiation is impossible. Those infections should not be regarded as intestinal only for in many cases the general features are of equal or more importance.

General Etiology.—Certain factors predispose to diarrhœa. AGE.—The largest number of cases occur just after the nursing period; the highest mortality is in the second half of the first year, when this period falls in the hot weather; hence the dread of the "second summer."

DIET.—Diarrhœa is most frequent in artificially fed babies. Of 1,943 fatal cases collected by Holt, only 3 per cent. were breast-fed. The agitation for pure milk in the large cities has decreased materially the number of diar-

rhœa cases among bottle-fed infants. Among the poor artificial feeding plays a large part due either to milk ill-suited in quantity or poor in quality, or to indigestible articles of diet. Many of the fatal cases have been fed upon condensed milk.

TEMPERATURE.—The relation of the atmospheric temperature to the prevalence of the disease in children has long been recognized. The mortality curve begins to rise in May, increases in June, reaching the maximum in July, and gradually sinks through August and September. The maximum corresponds closely with the highest mean temperature, yet we can not regard the heat itself as the direct agent, but only as one factor. Thus the mean temperature of June is only four or five degrees lower than that of July, and yet the mortality is not more than one-third. Neither barometric pressure nor humidity appears to have any influence.

BACTERIOLOGY.—The discovery by Duvall and Bassett of the dysentery bacillus in the dejecta of children suffering from summer diarrhœa awakened renewed interest and the Rockefeller Institute research showed that this organism was present in a large number of cases of so-called "summer diarrhœa." The causal connection of this group of bacteria with all the diarrhœal diseases of children has not been proved. By some workers they have been found in the fœces of a large proportion of all cases examined, and less frequently in the sporadic diarrhœas occurring throughout the year. These organisms occur in the acute primary intestinal infection in children, in subacute infection without previous symptoms coincident with or following other acute diseases such as measles, etc., and in the terminal intestinal infection following malnutrition or marasmus. They have been found in breast-fed infants as well as bottle-babies.

The mode of entrance of the organism can not always be determined. Simultaneous cases in remote parts of a community where there is no common milk supply, and occurrence of the disease in breast- and condensed-milk-fed babies, indicate that cow's milk is not the only conveyor of the infection, and point to other causes, possibly water, as a means of contamination.

The importance of other organisms must not be overlooked. There is a remarkable simplicity of bacterial flora in the intestines of healthy milk-fed children, *B. aërogenes* being present in the upper portion of the bowel and *B. coli* in the lower bowel, each almost in pure culture. When diarrhœa is set up the number and varieties of bacteria are greatly increased, although no forms bear a constant or specific relationship to the diarrhœa. Some diarrhœas in children are apparently induced by the lactic acid organisms in milk, others by *colon* or *proteus bacilli*, and others by the *pyogenic cocci* and other forms; all these bacteria may be associated with the dysentery bacilli. There is evidence to support the view that destructive lesions of the intestines may be produced by streptococci after an initial infection with a member of the dysentery group.

Morbid Anatomy.—In mild cases there may be only a slight catarrhal swelling of the mucosa of both small and large bowel, with enlargement of the lymph follicles. The mucous membrane may be irregularly congested; often this is most marked at the summit of the folds. The submucosa is usually infiltrated with serum and small round cells. In more severe cases ulceration may take place. The loss of substance begins, usually, in the

mucosa, over swollen lymph follicles. About the ulcer there is a more or less distinctly marked inflammatory zone. The destruction of the tissue is limited to the region of the follicles and becomes progressive by the union of adjoining ulcers. This process is usually confined to the lower bowel, and may be so extensive as to leave only ribbons of intact mucosa. The ulcers never perforate. Rarely there is a croupous or pseudo-membranous enteritis affecting the lower ileum, colon, and rectum with an increased secretion of mucus and lymphoid hyperplasia. The mesenteric glands are enlarged.

The changes in the other organs are neither numerous nor characteristic. Broncho-pneumonia occurs in many cases. The liver is often fatty, the spleen may be swollen. Brain lesions are rare; the membranes and substance are often anæmic, but meningitis or thrombosis is very uncommon.

Clinical Forms.—**ACUTE ENTERITIS.**—This form occurs in children of all ages, and is associated with infection or improper food. The symptoms often begin abruptly with nausea and vomiting, or, especially in stronger children, several hours or a day or two after the disturbing diet. The local symptoms are colicky pains, moderate tympanites, and diarrhœa. The stools are four to ten in twenty-four hours; at first faecal, then fluid, with more or less mucus and particles from undigested material. There is no blood. The usual intestinal bacteria are found. Occasionally, when there is mucus, dysentery bacilli are present. There is always fever. It is rarely very high, and never continues. The pulse may be rapid and the prostration marked in very young or weak children. These symptoms usually subside shortly after the emptying of the bowel. In weakened infants, or when treatment has been delayed or the diet remains unchanged, this disturbance may lead to more serious conditions. The attacks tend to recur.

FERMENTATIVE DIARRHŒA.—This form is characterized by more severe constitutional symptoms. It may begin after an intestinal indigestion of several days in which the stools are fluid and offensive, and contain undigested food and curds. In other cases the disease sets in abruptly with vomiting, griping pains, and fever, which may rapidly reach 104° — 105° F.

Nervous symptoms are usually prominent. The child is irritable and sleeps poorly. Convulsions may usher in the acute symptoms or occur later. An increasing drowsiness, ending in coma, has been noted in many cases. The stools, which vary from four to twenty in twenty-four hours, soon lose their faecal character and become fluid. Later they consist largely of green or translucent mucus. An occasional fleck of blood is noticed in the mucus, but this is never present in large amounts. Microscopically, besides the food residue and mucous strands are a moderate number of leucocytes and red blood-corpuscles. Epithelial cells are found with numerous bacteria.

The acute symptoms generally pass away in a few days with judicious treatment. Relapses are frequent, following any indiscretion. The attack may be the beginning of severe ileo-colitis. These gastro-intestinal intoxications are largely confined to the summer months and form an important group of the summer diarrhœas of children.

CHOLERA INFANTUM.—This term should be reserved for the fulminating form of the disease. The typical cases are rare and form only a small proportion of the diarrhœal diseases of infants. The attack sets in with vomiting, which is incessant and is excited by an attempt to take food or drink.

The stools are profuse and frequent; at first fæcal in character, brown or yellow in color, and finally thin, serous, and watery. The stools first passed are very offensive; subsequently they are odorless. The thin, serous stools are alkaline. There is fever and from the outset marked prostration; the eyes are sunken, the features pinched, the fontanelles depressed, and the skin has a peculiar ashy pallor. At first restless and excited, the child subsequently becomes heavy, dull, and listless. The tongue is coated at the onset, but subsequently becomes red and dry. As in all choleraic conditions, the thirst is insatiable; the pulse is rapid and feeble, and toward the end becomes irregular and imperceptible. Death may occur within twenty-four hours, with collapse and great elevation of the internal temperature. Before the end the diarrhœa and vomiting may cease. In other instances the intense symptoms subside, but the child remains torpid and semi-comatose, with fingers clutched, and there may be convulsions. The head may be retracted and the respirations interrupted, irregular, and of the Cheyne-Stokes type. The child may remain in this condition for some days without any signs of improvement. It was to this group of symptoms in infantile diarrhœa that Marshall Hall gave the term "hydrecephaloid," or spurious hydrocephalus. As a rule, no changes in the brain or other organs are found. The condition of sclerema is described as a sequel of cholera infantum. The skin and subcutaneous tissue becomes hard and firm, and the appearance has been compared to that of a half-frozen cadaver.

No constant organism has been found and Baginsky considers the disease the result of the action of the poisonous products of decomposition encouraged by the various bacteria present—a *Faulniss* disease. The clinical picture is that produced by an acute bacterial infection, as in Asiatic cholera.

Diagnosis.—The diagnosis is readily made. There is no other intestinal affection in children for which it can be mistaken. The constant vomiting, the frequent watery discharges, the collapse symptoms, and the elevated temperature make an unmistakable clinical picture. The outlook in the majority of cases is bad, particularly in children artificially fed. Hyperpyrexia, extreme collapse, and incessant vomiting are the most serious symptoms.

ENTERO-COLITIS.—In this form there is evidence of an inflammatory alteration of the intestinal wall, usually of the lower ileum and large intestine. Several sub-varieties are recognized according to the nature and site of the lesions. Many of the cases are grafted on the simple forms above described. The mucous discharges continue, mingled with food residue, often streaked with blood and containing pus cells. The temperature remains elevated or may be remittent. After two or three weeks the symptoms gradually subside, the stools become fewer in number, and the fæcal character returns.

In other instances severe involvement seems evident within a few hours of the onset, with abdominal pain, vomiting, and fever. Blood and pus may be present in nearly every stool. Tenesmus is frequent and prolapsus ani is not uncommon. In severe attacks the prostration is marked, the tongue is dry, the mouth covered with sordes, and death may ensue in a few days from profound sepsis, or the patient may continue desperately ill for weeks and gradually recover or die from asthenia.

Hæmorrhage of large amount is extremely rare. The appearance of bright red stains on the napkin indicates, usually, ulceration of the lower bowel or

rectum. When the blood is dark brown the lesion is in the ileum or near the valve. The extent of the ulceration can not be accurately determined by the quantity of the blood passed.

Membranous-colitis is usually only to be distinguished by the discovery of the membrane in the rectum through a speculum or in prolapsus, or by the passage of membrane in the stools. Colitis often occurs in marantic infants. It may consist of a catarrhal or follicular inflammation of the lower bowel without destructive lesion, and is frequently a terminal infection.

Enterocolitis may become chronic and persist for months. The signs of active inflammation subside; there is little pain or fever, but more or less mucus remains in the stools. The general condition suffers. There is a continuous loss in weight; the skin is dry and hangs in folds; nervous symptoms are always present. There may be stiffness and contraction of the extremities, with opisthotonos. The progress is irregular, marked by short periods of improvement. Death is often due to a relapse, asthenia, or broncho-pneumonia. In many of these cases, both acute and chronic, the dysentery bacilli have been found with other organisms. In all these forms *acidosis* may occur and should always be kept in mind. Increase in the respiration rate, for which no other explanation is found, should excite suspicion of this.

Prevention.—Unquestionably, most of the intestinal disorders of children can be prevented. In many large cities the mortality from the summer diarrhoeas has been greatly reduced by prophylactic measures. The infant should have abundance of air-space in the home, with plenty of sunlight and fresh air. In hot weather it may be well for him to sleep out of doors, day and night. The clothing must not be too heavy in midsummer; often only a binder and thin dress. This clothing should be altered with every change of the temperature. The greatest cleanliness should be demanded in the care and preparation of food, and of the feeding utensils and nurse's hands. Breast-feeding is continued whenever possible.

With bottle-babies, in warm weather, the diet should be reduced in strength—i. e., weaker milk mixtures used and more water given. In all crowded communities the milk should be pasteurized and all the water given the baby, either with or between the nourishment, boiled. It is better that a child should be in the country during hot weather, but when this is impossible the parks in the large cities afford much relief.

Treatment.—HYGIENIC MANAGEMENT.—Even after the illness has begun, much can be done by hygienic measures to diminish the severity. Change of air to seashore or mountain is often followed by a marked improvement in the child's condition. The patient must not be too warmly clad. The temperature may be lowered and nervous symptoms allayed by hydrotherapy. Baths and packs, warm and cool, are helpful. Colon irrigations are of great value and should be given cool when there is much fever.

DIET.—The dietetic management is of the utmost importance. In acute cases with fever all food must be stopped at once. It is best to give the infant nothing but water for several hours, it may be for two or three days, or until the acute symptoms subside; a cereal water may then be substituted, to which may be added egg albumen, broth, glucose or beef juice. The time at which it is safe to return to a milk diet varies with each case, and no

definite rules can be laid down. It is usually better to defer milk until the temperature is nearly normal.

If the stools are alkaline from protein decomposition, a diet consisting largely of carbohydrates—e. g., barley water—is indicated; whereas protein diet, such as beef juice and egg albumen, is more helpful when the stools are strongly acid.

The ingredient in the milk that is not well borne is the fat; hence skimmed milk, diluted or partially digested, can often be safely given before diluted whole milk. Whey is often helpful. Buttermilk may be used in convalescence from intestinal disturbances. The various proprietary foods, or condensed milk mixed with water, although not to be given over long periods, may be found serviceable in the gradual return to a normal diet.

In children from three to seven years of age these acute derangements are rarely serious, and usually respond promptly after purgation and restricted diet, consisting largely of boiled milk.

It must be borne in mind that injudicious treatment, either in diet or medication, may interrupt what otherwise would be a prompt recovery and bring on the most serious intestinal lesions. The chronic cases, both in infants and older children, especially those with ileo-colitis and ulceration, present unusual difficulties. Each case must be studied by itself. Food which is digested in the upper portion of the intestinal tract is preferable. Milk, properly modified with cereal water or predigested, if intelligently prescribed, offers the best chance of success. The percentage system of milk modification is of great service in feeding these long-standing cases.

Care must be taken not to over-feed, although occasionally, when there is persistent anorexia, gavage may be necessary. This is best accomplished through a nasal tube. Some infants will retain food given through a catheter when they will vomit the same mixture taken from a bottle. Beef juice is frequently useful. It should always be given with considerable fluid.

MEDICINAL.—In all cases of diarrhœa there are more or less congestion of the mucosa, hypersecretion of mucus, and increased peristalsis. In certain forms toxic symptoms are noticed early. In other instances inflammatory lesions in the bowel are present. The keynote of the treatment is promptness. Nature's effort to remove the disturbing cause should be assisted, not checked.

Castor oil and calomel are to be preferred as purgatives, especially for infants. A dram (4 c. c.) of the former, repeated, if necessary, will usually sweep the intestinal tract and relieve the irritation. Where there is much nausea or intestinal fermentation, calomel is indicated. It may be given in divided doses at short intervals until one grain (0.065 gm.) has been taken, or until the characteristic green stools appear. Very early in the attack, if nausea is marked, nothing relieves so quickly as gastric lavage with warm water or a weak soda solution. In older children a large draught of boiled water may be substituted. In many cases irrigation of the lower bowel with salt solution removes the irritating material and diminishes the absorption of toxins. It also reduces the temperature and allays nervous symptoms. The irrigating fluid should be cool when there is much fever. The infant is placed in the dorsal position or turned a little to the left, with hips elevated, and the fluid from a fountain syringe, about two feet above the patient, is allowed to flow into the rectum through a large soft rubber catheter. Usually about

a pint can be retained before expulsion. Two or three quarts should be used at one irrigation, which may be repeated several times in twenty-four hours if it is beneficial.

Where there is ulceration of the lower bowel various astringents, such as alum, witch hazel (one or two teaspoonfuls to one quart), silver nitrate, 1-5,000, or a weak solution of permanganate of potassium, may be used as the irrigating fluid. In great local irritation and tenesmus, enemata (2 ounces, 60 c. c.) of flaxseed or starch, with 2 to 5 drops (0.12 to 0.3 c. c.) of laudanum, are soothing and beneficial.

Water should be given freely by whichever method is indicated. With signs of *acidosis*, as much water as possible should be given and sodium bicarbonate in doses of gr. xv-xxx (1-2 gm.) by mouth or by the bowel every two hours, until the urine is alkaline. When there is much loss of fluid from the body or when toxic symptoms are marked normal salt solution should be given subcutaneously (200-300 c. c.).

Of the many drugs vaunted as intestinal astringents and antiseptics, bismuth, either as subgallate or subnitrate, has proved most serviceable. It should not be given until the disturbing material has been removed and the temperature is falling; then it should be administered in doses of 5 to 10 grains (0.3 to 0.6 gm.) every hour, until there is discoloration of the stools. Opium should be very sparingly used, and then only for a specific purpose, to check excessive peristalsis, violent colic, or very numerous passages. It may be given to an infant as Dover's powder, $\frac{1}{4}$ -1 grain (0.016 to 0.065 gm.); or paregoric, 5-10 minims (0.3 to 0.6 c. c.) every four hours; or morphia, hypodermically, 1/200-1/50 grain (0.0003 to 0.0013 gm.), when prompt action is desired. Occasionally it is well to combine it with atropine, 1/1,000-1/250 grain (0.000065-0.00026 gm.). The bowels should not be locked when the stools are foul or the temperature is high. When there is prostration stimulating treatment is indicated.

SERUM THERAPY.—The results of serum therapy have been disappointing. It is only in the very early stages that any improvement results. The marked reduction in the mortality in adult dysentery should encourage the further trial of this treatment.

TREATMENT OF CHOLERA INFANTUM.—In this serious symptoms may occur with great rapidity, and the incessant vomiting and frequent purging render the administration of remedies extremely difficult. Irrigation of the stomach and large bowel is of great service, and when the fever is high ice-water injections may be used, or a graduated bath. As in the choleraic diarrhoea of adults, morphia hypodermically gives the greatest relief, and with extreme vomiting and purging, with restlessness and collapse symptoms, this drug alone commands the situation. A child of one year may be given from 1/100 to 1/80 of a grain (0.00065 to 0.0008 gm.) to be repeated in an hour, and again if necessary.

In all cases of diarrhoea convalescence requires very careful management. An infant which has suffered from a severe attack should be especially watched throughout the remainder of the hot weather. During this time it is rarely safe to return to a full diet.

III. APPENDICITIS

Inflammation of the vermiform appendix is the most important of acute intestinal disorders. Formerly the "iliac phlegmon" was thought to be due to disease of the cæcum—typhlitis—or of the peritoneum covering it—perityphlitis; but we now know that with rare exceptions the cæcum itself is not affected. The contribution of Fitz in 1886 served to put the whole question on a rational basis. For historical and special details the reader is referred to the monograph of Kelly and Hurdon.

Etiology.—The exciting causes of appendicitis are not always evident. An infection is the essential factor. The lumen of the appendix forms a sort of test-tube, in which fæces lodge and are discharged with difficulty so that the mucosa is liable to injury from the inspissated fæces or occasionally foreign bodies. The anatomical features of the appendix render it liable to ulceration, strangulation and perforation. In some instances the appendicitis is a local expression of a general infection. The infection is often hæmatogenous and has its source in the mouth or throat. The causes of the increase of the disease are not known; one explanation is a lack of cellulose in the diet. Direct injury, as in straining and heavy lifting may be a rare exciting cause. Other conditions, tuberculosis and actinomycosis, may present the features of acute appendicitis. Cancer was found in 22 of 5,000 appendices removed at the Mayo Clinic and in 4 among 7,000 cases reported by Adams.

The BACTERIOLOGY is most varied. The *B. coli* is present in a large number of cases, and pyogenic organisms, particularly the *Streptococcus pyogenes*. A fresh conception of its relationship is suggested by the work of Rosenow. The dominant parasite in appendicitis is the colon bacillus, either in pure culture or with streptococci and staphylococci; the former chiefly in the lumen, the latter in the walls of the tube. Rosenow claims that in most cases appendicitis is a blood infection secondary to a distant focus such as the tonsil: and it would appear that certain streptococci have an elective affinity for the appendix. In 19 of 29 animals appendicitis was produced by injection of human tonsillar strains of organisms.

AGE.—Appendicitis is a disease of youth, 50 per cent. of the cases occurring before the twentieth year. It has occurred as early as the seventh week, but is rare prior to the fifth year. Of 1,223 cases at the Johns Hopkins Hospital only 9 cases were under 5 years, 59 in children under 10, 140 between 11 and 15, 199 between 16 and 20, and 255 between 21 and 25 (Churchman).

SEX.—It is about equally common in males and in females.

In England since 1901 the mortality has increased from 38 per million to 73 in 1928. There is an increase in the years of high diarrhoeal mortality. The figures do not bear out any belief that the increased frequency is a result of changes in diet. There were 15,618 deaths in the registration area of the United States in 1925, a rate of 151 per million.

Indiscretions in diet are very prone to bring on an attack, particularly in the recurring form of the disease, in which pain in the appendix region not infrequently follows the eating of indigestible articles of food.

Varieties.—McCarty from a study of 5,000 appendices removed at the Mayo clinic makes the following classification:

(a) APPENDICITIS CATARRHALIS ACUTA, a condition in which the mucosa

is infiltrated with leucocytes and congested with inflammatory reaction in the lymph follicles and lymphatic tissues of the submucosa.

(b) APPENDICITIS CATARRHALIS CHRONICA, following repeated mild or severe acute catarrh, marked by increase of scar tissue, and distortion of the normal regularity of the structure. Blood pigment is often present.

(c) APPENDICITIS PURULENTA NECROTICA, an advanced stage of the acute catarrhal condition, plus intramural abscesses, necrosis, and perforation.

(d) PERI-APPENDICITIS ACUTA, an extension to the peritoneum of the conditions just described.

(e) OBLITERATION, a condition of the lumen, the result of destruction of the mucosa and the formation of scar tissue, occurring in about 24 per cent. of all cases, and an inflammatory, not an involuntary, process.

There are cases, too, in which the appendix becomes sphacelated *en masse*, and may slough off.

Fæcal Concretions.—The lumen of the appendix may contain a mould of fæces, which can readily be squeezed out. Even while soft the contents of the tube may be moulded in two or three sections with rounded ends. Concretions are also common. Of 700 cases of foreign bodies there were 45 per cent. of fæcal concretions (J. F. Mitchell). The enteroliths often resemble date stones in shape. The importance of these concretions is shown by the great frequency with which they are found in acute cases.

Foreign Bodies.—In 1,400 cases of appendicitis (J. F. Mitchell) these were present in 7 per cent.; in 28 cases pins were found. Some of the concretions bear a striking resemblance to cherry and date stones.

Symptoms.—In a large proportion of all cases of acute appendicitis the following features are present: (a) Sudden pain in the abdomen, usually referred to the right iliac fossa; (b) fever, often of moderate grade; (c) gastro-intestinal disturbance—nausea, vomiting, and frequently constipation; (d) tenderness or pain on pressure in the appendix region.

PAIN.—A sudden, violent pain in the abdomen is the most constant, first, decided symptom of inflammation of the appendix, and occurred in 84 per cent. of the cases analyzed by Fitz. In fully half of the cases it is localized in the right iliac fossa, but it may be central or diffuse, but usually is in the right half of the abdomen. Even in the cases in which the pain is at first not in the appendix region it is usually felt here within thirty-six or forty-eight hours. It may extend toward the perineum or testicle. It is sometimes very sharp and colic-like, and cases have been mistaken for nephritic or for biliary colic. Some patients speak of it as a sharp, intense pain—serous-membrane pain; others as a dull ache—connective-tissue pain. In very severe cases, especially in children and with gangrene, there may be very little pain after the onset. While a very valuable symptom, pain is at the same time one of the most misleading. The appendicular colic is believed to be due sometimes to partial occlusion of the lumen, leading to violent and irregular peristaltic action.

FEVER.—Fever is usually present in the early stage, even in the mildest forms, and is a most important feature. An initial chill is very rare. The fever may be moderate, from 100° to 102°; sometimes in children at the very outset it may be above 103.5°. The thermometer is generally a most trustworthy guide in the diagnosis of acute appendicitis but in severe attacks

with gangrene there may be no fever, at any rate when the patient comes under observation. When a localized abscess has formed, and in some virulent cases of general peritonitis, the temperature may be normal, but at this stage there are other symptoms which indicate the gravity of the situation. The pulse is quickened in proportion to the fever and tends to increase as the condition progresses.

Elision
sh
tipat.
GASTRO-INTESTINAL DISTURBANCE.—The tongue is usually furred and moist, seldom dry. Nausea and vomiting may be absent, but are commonly present in acute cases. The vomiting rarely persists beyond the second day in favorable cases. Constipation is the rule, but the attack may set in with diarrhoea, particularly in children.

Lymphoid Hyperplasia.—This occurs in children or young adults, subjects of status lymphaticus, and is marked by repeated attacks of colic without any marked change in temperature or pulse rate, or leucocytosis (Symmers).

LOCAL SIGNS.—Inspection may show decreased movement of the lower right abdomen; there is no distention, and the iliac fossæ look alike. On palpation there is usually from the outset rigidity or muscle spasm of the right rectus muscle, with tenderness or pain on deep pressure. There may be hyperæsthesia of the skin. The muscular rigidity may be so great that a satisfactory examination can not be made without an anæsthetic. McBurney called attention to a localized point of tenderness on deep pressure, situated at the intersection of a line drawn from the navel to the anterior-superior spine of the ilium, with a second, vertically placed, corresponding to the outer edge of the right rectus muscle. Firm, deep, continuous pressure with one finger at this spot causes pain, often very severe. In addition to the tenderness, rigidity, and actual pain on deep pressure, there is to be felt, in some cases, an induration or swelling. This may be a boggy, ill-defined mass in the situation of the cæcum; more commonly the swelling is circumscribed and definite, situated in the iliac fossa, two or three fingers' breadth above Poupart's ligament. Some claim to have felt the thickened appendix. The later the case comes under observation the greater the probability of the existence of a well-marked tumor mass. In children the symptoms are often very acute with severe pain, vomiting and high fever. The pain is often increased on urination, defæcation or when the child is placed in a sitting position. The pain is more often on the left side than in adults, and urinary symptoms are common, as the appendix is frequently close to the bladder. Rectal examination may be of great aid in diagnosis. In patients in whom the appendix is situated behind the colon the symptoms may be referred to the upper right abdomen and simulate gall-bladder disease. There may be marked rigidity in the flank.

The attitude is often suggestive; the decubitus is dorsal with the right leg semi-flexed. Pulling on the right spermatic cord may cause pain. There may be tenderness of skin areas elicited by pinching or traction. The symptoms may be entirely pelvic when the appendix dips over the brim. Rectal or vaginal examination may give important information.

LEUCOCYTOSIS.—As a rule, in acute attacks there is a leucocytosis of 12,000 to 15,000, chiefly of the polynuclears. In mild catarrhal cases there may be no increase. Usually the degree is an expression of the peritoneal irritation. A low leucocytosis or leucopenia indicates a virulent infection.

There may be marked frequency of micturition, especially in children, which may be an early symptom. The urine is scanty and albuminuria is common. Sometimes there is an acute nephritis, and Dieulafoy described an acute toxic form. He thinks that the kidneys are not infrequently damaged in the disease.

There are three possibilities in any case: (1) Gradual recovery, (2) the formation of a local abscess, and (3) general peritonitis.

RECOVERY is the rule in the mild catarrhal cases. The pain lessens at the end of the second or third day, the temperature falls, the tongue becomes cleaner, the vomiting ceases, the local tenderness is less marked, and the bowels are moved. By the end of a week the acute symptoms have subsided.

LOCAL ABSCESS FORMATION.—As a result of ulceration and perforation, sometimes following the necrosis, by the end of the fourth or fifth day there is an extensive area of induration in the right iliac fossa, with great tenderness, and operations have shown that even at this early date an abscess may have formed. Though as a rule the fever becomes aggravated with the onset of suppuration, this is not always the case. The two most important elements in the diagnosis of abscess formation are the gradual increase of the local tumor and the aggravation of the general symptoms. Quite early the pus may lie between the cæcum and the coils of the ileum, with the general peritoneum shut off by fibrin, or there is a sero-fibrinous exudate with a slight amount of pus between the lower coils of the ileum. The abscess may be small and lie on the psoas muscle, or at the edge of the promontory of the sacrum, and never reach a palpable size. The sac, when larger, may be roofed in by the small bowel and present irregular processes and pockets leading in different directions. In larger collections in the iliac fossa the roof is generally formed by the abdominal wall. Some of the localized abscesses are situated entirely within the pelvis. The various directions and positions into which the abscess may pass or perforate are many and left alone, it may discharge externally, burrow in various directions, or be emptied through the rectum, vagina, or bladder. Death may be caused by septicæmia, by perforation into an artery or vein, or by pylephlebitis.

GENERAL PERITONITIS.—This may be caused by direct perforation or gangrene of the appendix before any delimiting inflammation is excited. In a second group of cases there has been an attempt at localizing the infective process, but it fails, and the general peritoneum becomes involved. In a third group of cases a localized focus of suppuration exists about an inflamed appendix, and from this perforation takes place.

Death in appendicitis is due usually to general peritonitis.

The gravity of appendix disease lies in the fact that from the very onset the peritoneum may be infected; the initial symptoms of pain, with nausea and vomiting, fever, and local tenderness may indicate a widespread infection of this membrane. The onset is usually sudden, the pain diffuse, not always localized in the right iliac fossa, but it is not so much the character as the greater intensity of the symptoms from the outset that makes one suspicious of a general peritonitis. Abdominal distention, diffuse tenderness, and absence of abdominal movements are the most trustworthy local signs, but they are not really so trustworthy as the general symptoms. The initial nausea and vomiting persist, the pulse becomes more rapid, the tongue is

dry, the urine scanty. In very acute cases, by the end of twenty-four hours the abdomen may be distended. By the third and fourth days the classical picture of a general peritonitis is well established—a distended and motionless abdomen, a rapid pulse, a dry tongue, dorsal decubitus with the knees drawn up, and an anxious, pinched, Hippocratic facies. The picture may be that of septicopyæmia: high fever, chills, sweats, without local signs. These are generally acute, gangrenous cases perhaps with an anomalous position of the appendix, behind the colon or deep in the pelvis. Sometimes there have been gastro-intestinal symptoms for a few days before, to which no attention has been paid. In one case, seen by the family physician at 2 p. m. for the first time, by the senior author at 4.30 p. m., at 7 p. m. by a surgeon who refused to operate, death occurred within 12 hours after the physician was first called.

Remote Effects.—The remote effects of perforative appendicitis are interesting. Hæmorrhage may occur. In one of our cases the appendix was adherent to the promontory of the sacrum, and the abscess cavity had perforated in two places into the ileum. Death resulted from profuse hæmorrhage. The internal iliac artery or the deep circumflex iliac artery may be opened. Suppurative pylephlebitis may result from inflammation of the mesenteric veins. Secondary liver abscess may occur. The appendix may perforate in a hernial sac. Distant disorders attributed to disease of the appendix are various types of gastric dyspepsia, ulcer, spasm of the pylorus, pancreatitis, bile tract infection and cirrhosis of the liver.

After operation, thrombosis of the iliac or femoral veins is not uncommon, and sudden death from pulmonary embolism has followed. The leg may be permanently enlarged. Hernia may occur in the wound. Strangulation of the bowel is an occasional sequence and adhesions about the cæcum may give trouble.

Chronic Appendicitis.—There may be recurring attacks, acute or sub-acute, to which this term may be applied, but in addition there is a group of cases in which the symptoms do not suggest disease of the appendix as they appear elsewhere. In such cases there may be a history of an acute attack of appendicitis many years before. The clinical picture may be variable but gastric symptoms are usually prominent. These are usually irregular but epigastric discomfort or pain is common, usually after meals. Nausea and flatulence are frequent but vomiting is not common and if it does occur rarely gives relief. The pain is epigastric or general more often than referred to the right iliac fossa. It varies from time to time but the patient is not long free from some discomfort. The signs are indefinite; there may be tenderness in the right iliac fossa or on pressure there discomfort is most marked in the epigastrium. Sometimes there is very localized tenderness on deep pressure over a small area. If the appendix is behind the colon the pain from pressure may be felt in the upper right quadrant of the abdomen. The results of test meals are variable, normal, hyper- or hyposecretion. There is usually marked constipation. If the appendix is in the pelvis there may be bladder irritability. The results of the X-ray study are important. When the appendix or its probable position is identified under the fluoroscope, palpation shows that this is the point of greatest tenderness and if the organ can be moved the site of tenderness moves also. Adhesions about the cæcum

suggest chronic appendicitis. By inflation of the colon with air tenderness over the appendix appears or is increased (Bastedo).

Diagnosis.—Appendicitis is by far the most common inflammatory condition in the abdomen in persons under thirty. The surgeons have taught us that, with few exceptions, sudden pain in the right iliac fossa, with fever and localized tenderness, means appendiceal disease. Pneumonia should always be excluded. There are certain diseases of the abdominal organs characterized by pain which may be confounded with appendicitis. Biliary colic, kidney colic, pyelitis, stricture of the right ureter and colicky pains at the menstrual period in women have to be carefully considered. The Dietl's crises in floating kidney have been mistaken for appendicitis.

Diseases of the tubes, rupture of an extra-uterine pregnancy, hæmorrhage into a Graafian follicle, an ovarian cyst with a twisted pedicle and pelvic peritonitis may simulate appendicitis very closely, but the history and the local examination under ether in most cases enable the practitioner to reach a diagnosis. Some cases supposed to be recurring appendicitis prove to be tubo-ovarian disease.

Acute hæmorrhagic *pancreatitis* may produce symptoms very like those of appendicitis with general peritonitis. The relation of typhoid fever and appendicitis is interesting. The gastro-intestinal symptoms, particularly the pain and fever, may at the onset suggest appendicitis. Operations have been comparatively frequent. Later in the course of typhoid fever perforation of the appendix may occur, and occasionally in convalescence perforation of an unhealed ulcer of the appendix. In young children *acetone acidosis* (cyclic vomiting) may give difficulty. There may be severe vomiting with abdominal pain, and the cæcum may be distended and tender. The smell of acetone on the breath and the urinary findings should distinguish. Acute *pyelitis* is recognized by the study of the urine. Inflammation of the ileo-cæcal lymph nodes may be accompanied by pain and vomiting with tenderness and rigidity in the right iliac fossa. The diagnosis may be difficult.

The recognition of *chronic appendicitis* may be very difficult. Thorough study and observation for a period are essential. The X-ray study is specially important. The distinction from gall-bladder disease may be obscure, in fact the two often occur together, especially in older patients. Pelvic disease should be carefully excluded. A calculus in the kidney or ureter, pyelitis, and especially *stricture of the ureter* should be excluded. The slight results from medical treatment and the long duration of symptoms are points of importance. Hysteria may simulate appendicitis very closely, and it may require a very keen judgment to make a diagnosis. Mucous colitis with enteralgia in nervous women is sometimes mistaken for appendicitis. Ulceration or partial obstruction of the descending colon may suggest appendicitis. The referred pain of acute thoracic disease, especially pneumonia and pleurisy, and the root pains of spondylitis have led to error, but this should not occur if a proper examination is made.

Perinephritic and pericæcal abscess from perforation of ulcer, either simple or cancerous, and circumscribed peritonitis in this region from other causes, can rarely be differentiated until an exploratory incision is made.

Briefly stated, localized pain in the right iliac fossa, with or without induration or tumor, the existence of McBurney's tender point, fever, furred

tongue, vomiting, with constipation or diarrhoea, indicate appendicitis. The occurrence of general peritonitis is suggested by increase and diffusion of the abdominal pain, tympanites (as a rule), marked aggravation of the constitutional symptoms, particularly elevation of fever and increased rapidity of the pulse. Obliteration of hepatic dulness is rarely present, as the peritoneum in these cases does not often contain gas.

Appendicitis and Pregnancy.—The association is not uncommon. Of 103 perforative or gangrenous cases 89 were operated upon, with 36 deaths. Of 14 cases not operated upon all died. Of the 103 cases 80 aborted before or after operation. Of 104 non-perforative cases 50 were operated upon with 1 death, of the remaining 54, 4 died; 13 of these patients aborted (Babler). Mild cases recover; in the severer form it is safer to operate at once.

Prognosis.—*There would be no percentage of deaths from appendicitis if every case commencing with acute pain and developing tenderness and rigidity of the abdomen and quickening of the pulse were operated upon within twelve hours* (Rutherford Morison).

While the majority of patients recover without operation it is never possible to predict the outcome at the onset of any attack. With early diagnosis and immediate operation the outlook is excellent. If peritonitis has set in the outcome is always uncertain. In the dangerous and perforative cases the outlook depends on the time of operation. After recovery from an attack without operation there is a strong probability of recurrence. It would be interesting to know how many of the 15,618 fatal cases in 1925 in the United States had been operated upon and at what period.

Treatment.—Gradually the profession has learned to recognize that appendicitis is a surgical disease. In hospital practice the patients should be admitted directly to the surgical wards. Many lives are lost by temporizing. The general practitioner does well to remember—whether his leanings be toward conservative or radical methods of treatment—that the surgeon is often called too late, never too early.

There is no medicinal treatment of appendicitis. There are no remedies capable in any way of controlling the course of the disease. Rest in bed, nothing by mouth, fluid by the drop method in the bowel, no purgation, the use of a small enema if necessary, gastric lavage if there is vomiting, are the wisest measures till a decision as to operation is reached. The practice of giving opium in some form in appendicitis and peritonitis is decreasing, but is still too common. The persistent use of ice locally may be employed to relieve the pain. Purgatives should not be given, even if there is only a suspicion of appendicitis.

If the patient is seen within thirty-six hours of the onset, immediate operation is advisable as recovery is almost certain and more dangerous developments are prevented. If acute peritonitis has begun the best surgical judgment may have difficulty in deciding as to operation. Operation is indicated in case of abscess.

In recurring appendicitis, when the attacks are of such severity and frequency as to disturb the patient, the mortality in capable hands is very small. It is best to operate between attacks. In the chronic variety operation should be done when the diagnosis is definite; it should not be done in a doubtful case on the chance of helping.

IV. INTESTINAL OBSTRUCTION

Intestinal obstruction may be caused by strangulation, intussusception, twists and knots, strictures and tumors, by abnormal contents, and by paralysis of the muscular coat of the bowel.

Etiology and Pathology.—(a) STRANGULATION.—This is the most frequent cause of acute obstruction, and occurred in 34 per cent. of the 295 cases analyzed by Fitz, and in 35 per cent. of the 1,134 cases of Leichtenstern. Of the 101 cases of strangulation in Fitz's table, which has the special value of having been carefully selected from the literature since 1880, the following were the causes: Adhesions, 63; vitelline remains, 21; adherent appendix, 6; mesenteric and omental slits, 6; peritoneal pouches and openings, 3; adherent tube, 1; peduncular tumor, 1. The bands and adhesions result, in a majority of cases, from former peritonitis. A number of instances have been reported following operations upon the pelvic organs in women. The strangulation may be recent and due to adhesion of the bowel to the abdominal wound or a coil may be caught between the pedicle of a tumor and the wall. Late occlusion after recovery from operation is due to bands and adhesions.

The vitelline remains are represented by Meckel's diverticulum, which forms a finger-like projection from the ileum, usually within eighteen inches of the ileo-cæcal valve. The coils of the intestine may be strangulated about the diverticulum when its end is attached to the abdominal wall, to the mesentery, or to another portion of the intestine, or a long diverticulum unattached may be twisted, or there may be inversion of the diverticulum into the lumen of the bowel causing obstruction or leading to intussusception.

Seventy per cent. of the cases of obstruction from strangulation occur in males; 40 per cent. of all the cases occur between the ages of fifteen and thirty years. In 90 per cent. of the cases of obstruction from these causes the site of the trouble is in the small bowel; the position of the strangulated portion was in the right iliac fossa in 67 per cent. of the cases, and in the lower abdomen in 83 per cent.

(b) INTUSSUSCEPTION.—In this condition one portion of the intestine slips into an adjacent portion, forming an invagination or intussusception. Irregular peristalsis is the essential cause. The two portions make a cylindrical tumor, which varies in length from a half inch to a foot or more. The condition is always a descending intussusception, and, as it proceeds, the middle and inner layers increase at the expense of the outer layer. An intussusception consists of three layers of bowel: the outermost, the intussusciens, or receiving layer; a middle or returning layer; and the innermost or entering layer. The student can obtain an idea of the arrangement by making the end of a glove-finger pass into the lower portion. The actual condition can be studied in the common post mortem invaginations in the small bowel of children. In the statistics of Fitz, 93 of 295 cases of acute intestinal obstruction were due to this cause. Of these, 52 were in males and 27 in females. The cases are most common in early life, 34 per cent. under one year and 56 per cent. under the tenth year. Of 103 cases in children, nearly 50 per cent. occurred in the fourth, fifth, and sixth months (Wiggin). No definite cause could be assigned in 42 of the cases; in the others diarrhœa or habitual constipation had existed.

The site of the invagination varies. We may recognize (1) an ileo-cæcal, when the ileo-cæcal valve descends into the colon, probably favored by atony of the ileo-cæcal valve. There are cases in which this is so extensive that the valve has been felt *per rectum*. This form occurred in 75 per cent. of the cases; in 89 per cent. of Wiggan's collected cases. In the ileo-colic the lower part of the ileum passes through the ileo-cæcal valve. (2) The ileal, in which the ileum is alone involved. (3) The colic, in which it is confined to the large intestine. (4) Cylico-rectal, in which the colon and rectum are involved. (5) Intussusception of the appendix is rare, but there are cases on record, most of them in children.

In case of death from intussusception, the condition is very characteristic. Peritonitis or acute injection of the serous membrane may be present. When death occurs early, as it may from shock, there is little to be seen. The portion of bowel affected is large and thick, and forms an elongated tumor with a curved outline. The parts are swollen and congested, owing to the constriction of the mesentery between the layers. The entire mass may be of a deep livid-red color. In very recent processes there is only congestion, and perhaps a thin layer of lymph, and the intussusception can be reduced, but when it has lasted for a few days, lymph is thrown out, the layers are glued together, and the entering portion of the gut can not be withdrawn.

The anatomical condition accounts for the tumor present in two-thirds of all cases; and the engorgement, which results from the compression of the mesenteric vessels, explains the frequent occurrence of blood in the discharges, which has so important a diagnostic value. If the patient survives, necrosis and sloughing of the invaginated portion may occur, and, if union has taken place between the inner and outer layers, the calibre of the gut may be restored and a cure effected. Many cases are on record. In the museum of McGill University are 17 inches of small intestine, passed by a lad who had symptoms of internal strangulation, and who made a complete recovery.

(c) VOLVULUS.—Volvulus or twist occurred in 42 of 295 cases (Fitz); 68 per cent. were in males. It is most frequent between the ages of thirty and forty. In the great majority of cases the twist is axial and associated with an unusually long mesentery. In 50 per cent. of the cases it was in the sigmoid flexure. The next most common situation is about the cæcum, which may be twisted upon its axis or bent upon itself. Constipation is an important etiological factor. As a rule, in volvulus the loop of bowel is simply twisted upon its long axis, and the portions at the end of the loop cross each other and so cause strangulation. It occasionally happens that one portion of the bowel is twisted about another.

Traction kinks occur at three regions—the third portion of the duodenum, the last part of the ileum, and the sigmoid flexure. What is known as gastro-mesenteric ileus is caused by compression of the lower portion of the duodenum by the root of the mesentery with its contained blood-vessels. The condition has been described under acute dilatation of the stomach.

The ileum kink occurs within a few inches of the cæcum. This portion has a short tight mesentery and a large loose cæcum may sag over the brim of the pelvis and cause a definite kink of the ileum with constipation, pain in the right iliac fossa, and symptoms which simulate appendicitis.

Traction of a very full sigmoid flexure may, without any special twist, compress and obstruct a neighboring coil of the colon.

(d) STRICTURES AND TUMORS.—These are less important causes of *acute* obstruction, as may be judged by the fact that there are only 15 instances out of 295 cases, in 14 of which the obstruction occurred in the large intestine (Fitz). They are common causes of *chronic* obstruction. Lipoma may occur, growing from the submucosa, and cause intussusception. In a number of cases the tumor has been passed *per rectum*. S. B. Ward collected 9 cases.

The obstruction may result from: (1) *Congenital stricture*. These are exceedingly rare. Much more commonly the condition is that of complete occlusion, either forming the imperforate anus or the congenital defect by which the duodenum is not united to the pylorus. (2) *Simple cicatricial stenosis*, which results from ulceration, tuberculous or syphilitic, and more rarely from dysentery. (3) *New growths*. The malignant structures are due chiefly to cylindrical epithelioma, which forms an annular tumor, most common in the large bowel, about the sigmoid flexure, or the descending colon. Of benign growths, papillomata, adenomata, lipomata, and fibromata occasionally induce obstruction. (4) *Compression and traction*. Tumors of neighboring organs, particularly of the pelvic viscera, may cause obstruction by adhesion and traction. In the healing of tuberculous peritonitis the contraction of the thick exudate may cause compression and narrowing of the coils.

(e) ABNORMAL CONTENTS.—*Foreign bodies*, such as fruit stones, coins, pins, or false teeth, are occasionally swallowed. *Round worms* may become rolled into a tangled mass and cause obstruction. In reality, the majority of foreign bodies, such as coins, and pins, cause no inconvenience, but in a day or two pass in the stools. Occasionally such a foreign body as a pin passes through the œsophagus and lodges in some adjacent organ, as in the heart (Peabody), or a barley ear may reach the liver (Dock).

Drugs, such as magnesia or bismuth, have accumulated in the bowels and produced obstruction, but in the great majority of the cases the condition is caused by fæces, gall-stones, or enteroliths. Of 44 cases, in 23 the obstruction was by gall-stones, in 19 by fæces, and in 2 by enteroliths. Obstruction by fæces may happen at any period of life; it may occur in young children and persist for weeks. In fæcal accumulation the large bowel may reach an enormous size and the contents become very hard. The retained masses may be channeled, and small quantities of fæcal matter are passed until a mass too large enters the lumen and causes obstruction. There may be few symptoms, as the condition may be borne for weeks or even for months.

Obstruction by gall-stones is not very infrequent, as 23 cases were reported in the literature in eight years. Eighteen of these were in women and 5 in men. In six-sevenths of the cases it occurred about the fiftieth year. The obstruction is usually in the ileo-cæcal region, but it may be in the duodenum. These large gall-stones ulcerate through the gall-bladder, usually into the small intestine, occasionally into the colon. In the latter case they rarely cause obstruction. Courvoisier collected 131 cases in the literature.

Enteroliths may be formed of masses of hair, more commonly of the phosphates of lime and magnesia, with a nucleus formed of a foreign body or of hardened fæces. Nearly every museum possesses specimens of this kind.

They are not so common in men as in ruminants, and, as indicated in Fitz's statistics, are very rare causes of obstruction.

(f) PARALYTIC ILEUS.—Without any obstruction in the lumen, in a localized area or in a wide section of the bowel, the muscular walls may be so paralyzed that no movement of the contents occurs, causing a condition which virtually amounts to obstruction. The best illustrations of local paralytic ileus are seen in the embolic and thrombotic processes in the mesenteric arteries, when the corresponding portions of the intestinal wall are in a state of infarction. This occurs in the verminous aneurism in a horse and is associated with intestinal colic. It is more common in the small than in the large bowel, but in one instance of paralytic ileus due to involvement of eight inches of the transverse colon there was not, so far as one could discover, any affection of the blood-vessels; the symptoms were those of acute obstruction.

Following operations, particularly on the abdomen, after injuries, following paracentesis in ascites, in pneumonia, pleurisy, and occasionally in heart disease, a paralytic state of the bowel may occur, with cessation of peristalsis, distention of the abdomen, vomiting, and other signs of obstruction. There are remarkable cases of hysteria with symptoms of chronic obstruction of the bowels and fæcal vomiting—the so-called ileus hystericus.

Symptoms.—(a) ACUTE OBSTRUCTION.—Pain, vomiting, constipation and collapse are the important features. Pain sets in early and may come on abruptly while the patient is walking, or, more commonly, during the performance of some action. It is at first colicky in character, but subsequently becomes continuous and very intense. Vomiting follows quickly and is constant and most distressing. At first the contents of the stomach are voided, and then greenish, bile-stained material, and later the material vomited is a brownish-black liquid, with a distinctly fæcal odor. This sequence of gastric, bilious, and, finally, stercoraceous vomiting is a most important diagnostic feature of acute obstruction. The higher the obstruction is in the bowel, the more severe the vomiting. The constipation may be absolute, without the discharge of either fæces or gas. Very often the contents of the bowel below the stricture are discharged. Distention of the abdomen usually occurs, and, when the large bowel is involved, it is extreme. On the other hand, if the obstruction is high up in the small intestine, there may be very slight tympany. At first the abdomen is not tender, but subsequently it may become acutely so. A tumor may be felt, especially in intussusception. If acute obstruction occurs secondary to chronic obstruction there may be marked peristalsis.

The constitutional symptoms from the outset are severe. The face is pallid and anxious, and collapse supervenes. The eyes become sunken, the features pinched, and the skin is covered with a cold, clammy sweat. The pulse becomes rapid and feeble; the blood pressure falls. There may be no fever. Toxæmia is marked. The tongue is dry and parched and the thirst is incessant. The urine is high-colored, scanty, and there may be suppression, particularly when the obstruction is high up in the bowel. This is probably due to the constant vomiting and the small amount of liquid absorbed. There is an increase in the non-protein nitrogen of the blood, more rapid if the obstruction is high. The case terminates, as a rule, in from three to six

days. In some instances the patient dies from shock or sinks into coma. A leucocytosis of 75,000 or 80,000 may be present.

(b) CHRONIC OBSTRUCTION.—When due to *faecal impaction*, there is a history of long-standing constipation. There may have been discharge of mucus, or, in some instances, the faecal masses have been channeled, and so have allowed the contents of the upper portion of the bowel to pass through. In elderly persons this is not infrequent; but examination, either *per rectum* or externally, in the course of the colon, will reveal the presence of hard scybalous masses. There may be retention of faeces for weeks without exciting serious symptoms. In other instances there are vomiting, pain in the abdomen, gradual distention, and finally the ejecta become faecal. The hardened masses may excite an intense colitis or even peritonitis.

Chronic intussusception is rare, occurs in adults and may be associated with tumors or polypi. The symptoms may be intermittent; attacks of colic occur with constipation and possibly the passage of mucus and blood. A tumor is palpable in some cases and may be more marked during acute exacerbations; occasionally it reaches the anus. There is always danger of acute obstruction or peritonitis.

In *stricture*, whether cicatricial or cancerous, the symptoms are very diverse. Constipation gradually comes on, is extremely variable, and it may be months or even years before there is complete obstruction. There are transient attacks, in which from some cause the faeces accumulate above the stricture, the intestine becomes greatly distended, and in the swollen abdomen the coils can be seen in active peristalsis. In such attacks there may be vomiting, but it is very rarely faecal. In the majority of these cases the general health is seriously impaired; the patient gradually becomes anæmic and emaciated, and, finally, in an attack of complete obstruction, death occurs with the features of acute occlusion, or the course may be prolonged for ten or twelve days.

Diagnosis.—The diagnosis of obstruction does not offer great difficulty in the majority of cases but some conditions simulate it closely. *Acute enteritis* with severe vomiting and pain may give difficulty, but the diarrhoea makes the diagnosis clear. *Peritonitis* may cause confusion, but the local signs in the abdomen, the absence of peristalsis, and the general features should aid. In obstruction, peritonitis occurs in the later stages, and if the patient is seen then for the first time the recognition of the obstruction may be difficult. *Acute pancreatitis* may simulate obstruction very closely as also *mesenteric thrombosis* or *embolism*. The diagnosis may be in doubt until the abdomen is opened. *Lead poisoning* should not cause difficulty if a careful study is made; the blue line on the gums, the absence of vomiting, the milder character of the pain and the general condition are important. *Hernia* must always be excluded, which is not easy in fat patients. The possibility of a small femoral or pro-peritoneal hernia should be kept in mind. An obturator hernia can only be recognized after opening the abdomen. In some cases the necessary diagnosis is of a condition which demands exploration of the abdomen.

(a) THE SITUATION OF THE OBSTRUCTION.—A thorough rectal and, in women, a vaginal examination gives information as to the condition of the pelvic and rectal contents, particularly in intussusception, in which the descending bowel can sometimes be felt. In obstruction high up the empty coils

sink into the pelvis and can there be detected. In the inspection of the abdomen there are important indications, as the special prominence in certain regions, the occurrence of well-defined masses and hypertrophied coils in active peristalsis. John Wyllie called attention to the great value in diagnosis of the "patterns of abdominal tumidity." In obstruction of the lower end of the large intestine not only may the horseshoe of the colon stand out plainly, when the bowel is in rigid spasm, but even the pouches of the gut may be seen. When the cæcum or lower end of the ileum is obstructed the tumidity is in the lower central region, and during spasm the coils of the small bowel may stand out prominently, one above the other, either obliquely or transversely placed—the so-called "ladder pattern." In obstruction of the duodenum or jejunum there may only be slight distention of the upper part of the abdomen, associated usually with rapid collapse and anuria. The acute toxæmia may be due to proteose intoxication.

In the ileum and cæcum the distention is more in the central portion of the abdomen; the vomiting is distinctly fæcal and occurs early. In obstruction of the colon tympanites is much more extensive and general. Tenesmus is more common, with the passage of mucus and blood. The course is not so quick, the collapse does not supervene so rapidly, and the urinary secretion is not so much reduced.

In obstruction from stricture or tumor the situation can in some cases be accurately localized, but in others it is very uncertain. Digital examination of the rectum should first be made. The sigmoidoscope should be used cautiously. The quantity of fluid which can be passed into the large intestine should be estimated. For diagnostic purposes the rectum may be inflated with air. In certain cases these measures give important indications as to the situation of an obstruction in the large bowel. An X-ray examination should always be made.

(b) NATURE OF THE OBSTRUCTION.—This is often difficult, not infrequently impossible, to determine. *Strangulation* is not common in very early life. In many instances there have been previous attacks of abdominal pain, or there are etiological factors which give a clue, such as old peritonitis or operation on the pelvic viscera. Neither the onset nor the character of the pain gives us any aid. In rare instances nausea and vomiting may be absent. The vomiting usually becomes fæcal from the third to the fifth day. A tumor is not common in strangulation, and was present in only one-fifth of the cases. Fever is not of diagnostic value.

Intussusception is an affection of childhood, and is of all forms of internal obstruction the one most readily diagnosed. The onset is acute with pain and signs of shock after which the symptoms may decrease for a time. Vomiting is not constant. The presence of tumor, bloody stools, and tenesmus are the important factors. The tumor is usually sausage-shaped and felt in the region of the transverse colon. It existed in 66 of 93 cases. It became evident the first day in more than one-third of the cases, on the second day in more than one-fourth, and on the third day in more than one-fifth. Blood in the stools occurs in at least three-fifths of the cases, either spontaneously or following an enema. The blood may be mixed with mucus. Tenesmus is present in one-third of the cases. Fæcal vomiting is not very common and was

present in only 12 of the 93 instances. *Henoch's purpura* involving the bowel may give difficulty; signs of purpura may be found elsewhere.

Volvulus can rarely be diagnosed. The frequency with which it involves the sigmoid flexure is to be borne in mind. The injection of fluid may give valuable indications.

In *fæcal obstruction* the condition is usually clear, as the fæces can be felt *per rectum* and also in the distended colon. Fæcal vomiting, tympany, abdominal pain, nausea, and vomiting are late and are not so constant. In obstruction by gall-stone a few of the patients gave a previous history of gall-stone colic. Jaundice was present in only 2 of the 23 cases. Pain and vomiting, as a rule, occur early and are severe, and fæcal vomiting is present in two-thirds of the cases. A tumor is rarely evident.

Prognosis.—Recovery without operation results in a few cases, but as a rule death follows unless operation is done. Naturally the earlier the obstruction is relieved the better the outlook. The age, general condition and, in very acute cases, the degree of toxemia are important. Promptness in diagnosis and operative interference decide the outlook to a considerable extent.

Treatment.—In *acute obstruction* operation should be done at the earliest possible moment. In case of doubt or if operation is refused, nothing should be given by mouth, the stomach should be washed if there is vomiting or distention, nothing in the nature of a purgative should be given, and the colon may be irrigated very cautiously. Fluid can be given by the drop method by the bowel or subcutaneously. Morphia may be given to relieve the pain if operation is decided on or if the condition is hopeless. It should not be used while there is doubt, but hot or cold applications, as the patient prefers, made to the abdomen.

In *chronic obstruction* the diet should be concentrated. Enemata of various kinds may be tried cautiously but purgatives should not be given. The use of mineral oil is sometimes helpful. Belladonna or atropine should be given to diminish spasm; opium or morphia should be used only after careful consideration.

V. CONSTIPATION

Definition.—Delay in the passage of the contents of the intestines.

Etiology.—GENERAL CAUSES.—(a) Constitutional peculiarities: Constipation may be a family complaint, possibly due to congenital muscular weakness of the colon. (b) Sedentary habits, particularly in persons who eat too much and neglect the calls of nature. (c) Certain diseases, such as anæmia, neurasthenia, and hysteria, chronic affections of the liver, stomach, and intestines, and the acute fevers. (d) Diet, either one which gives an irritating residue causing spasm of the colon or one which leaves too little. (e) That most injurious of all habits, drug taking. The irritability produced by purgatives leads to disturbance of the mucous membrane and also of the sympathetic nervous system. (f) The most common cause is disturbance in the act of defæcation, frequently due to neglect. The fæces are moved down to the pelvic colon and normally the impulse to defæcate comes from the passage of this material into the rectum. Neglect of this impulse means that the sensation is gradually decreased, so that a stronger stimulus is required, or it

is lost entirely. Atony and dilatation of the rectum result, with accumulation of fæces in the colon which may result in spasmodic contraction or atony. The mental attitude is important; the individual thinks that his bowels will not move without help by drugs or enemata; the use of these in time renders normal function more difficult and so the vicious circle goes on.

LOCAL CAUSES.—Weakness of the abdominal muscles in obesity or from overdistention in repeated pregnancies. Atony of the large bowel from chronic disease of the mucosa; the presence of tumors, physiological or pathological, pressing upon the bowel; enteritis; foreign bodies, large masses of scybala, and strictures of all kinds. An important local cause is atony of the colon, particularly of the muscles of the sigmoid flexure by which the fæces are propelled into the rectum. An obstinate form is that associated with a contracted state of the colon (spastic constipation). This is met with—first, as a sequence of chronic dysentery or ulcerative colitis; secondly, in cases of hysteria and neurasthenia, usually with vagotonia; and, thirdly, in very old persons often without any definite cause. This form is common in those who have a nervous system easily disturbed. It may be that the sigmoid flexure and lower colon are in a spastic condition, while the transverse and ascending parts are in a state of atony and dilatation. The most characteristic sign of this variety is the presence of hard, globular masses, or small and sausage-like fæces.

Radiography has taught us much of the conditions favoring intestinal stasis. The upward position in man favors visceroptosis, with which we find associated many obstinate cases of constipation. Arbuthnot Lane has emphasized the fact of this dropping or dragging of the intestines, particularly at certain points—e. g., the third part of the duodenum, where there may be an abrupt kink with a considerable dilatation of the duodenum. This is relieved when the patient lies down. The second is the ileal kink, caused by a dropping of the cæcum, and the lower coil of the ileum. The obstruction may result in dilatation of the end of the ileum, with delay in the passage of the fæces. A third point is the fixed splenic flexure of the colon. The sigmoid loop seems specially designed to promote stasis; the rectum may also present an elongated S-shaped loop, and, finally, there is the sharp pelvi-rectal flexure, above which the fæces accumulate.

The rate of the passage of the fæces through the bowel may be estimated accurately with the X-rays. After a bismuth meal the cæcum is reached in about four hours, the hepatic flexure two hours later, the splenic flexure three hours after that, and the beginning of the pelvic colon twelve hours after the commencement of the meal. The fæces do not pass beyond the pelvi-rectal flexure until just before defæcation.

Hurst divides the causes into (1) delay in the passage through the colon with normal defæcation (*colic constipation*); (2) normal passage through the colon with difficulty in evacuation from the pelvic colon (*dyschezia*); and (3) insufficient formation of fæces.

SYMPTOMS.—It is difficult to state exactly what general symptoms are actually due to constipation. It occurs frequently in persons whose general and sympathetic nervous systems are disturbed. Many of the discomforts attributed to constipation are really due to sympathetic system disturbance and not to “intestinal auto-intoxication” about which so much nonsense has

been talked and written. This is shown by the fact that relief often follows immediately after the bowels have moved. A "toxæmia" could not disappear in such a short time. Persistent constipation may exist with good health, but there is no question that regular and sufficient emptying of the bowel is the normal and should be attained. Whether this means two or three stools in the day, or a daily movement, or one every two days depends on the individual.

Debility, lassitude, vertigo, and mental depression are frequent symptoms in constipation, particularly in persons of a nervous temperament. Headache, loss of appetite, a furred tongue, foul breath and gastric disturbance may occur. In girls the skin is "muddy," acne is common, anæmia may be associated, and there is a flabby state of the system generally.

When persistent, the accumulation of fæces leads to unpleasant, sometimes serious, local conditions, such as piles, ulceration of the colon, distention of the sacculi, perforation, enteritis, and occlusion. In women pressure may cause pain at the time of menstruation and a sensation of fullness and distention in the pelvic organs. Neuralgia of the sacral nerves may be caused by an overloaded sigmoid flexure. The fæces collect chiefly in the colon. Even in extreme grades of constipation it is rare to find dry fæces in the cæcum. The fæces may form large tumors at the hepatic or splenic flexures, or a sausage-like, doughy mass above the navel, or an irregular tumor in the left inguinal region. In old persons the sacculi of the colon become distended and the scybala may remain and undergo calcification, forming enteroliths. In cases with prolonged retention the fæcal masses become channeled and diarrhæa may occur for days before the true condition is discovered. In women who have been habitually constipated attacks of diarrhœa with nausea and vomiting should excite suspicion and lead to a thorough examination of the large bowel.

Captivated by the theories of Metchnikoff we have been for some years on the crest of a colonic wave, and "intestinal toxæmia" has been held responsible for many of the worst of the ills that flesh is heir to, more particularly arteriosclerosis and old age. The seniles and preseniles of two continents have been taking sour milk and lacto-bacillary compounds, to the great benefit of the manufacturing chemists! Much of what is regarded as intestinal toxæmia is really intestinal infection.

Constipation in infants is common and troublesome. The causes are congenital, dietetic, and local. In some instances the child is constipated from birth and may not have a natural movement for years, and yet thrive and develop. There are cases of enormous dilatation of the colon with persistent constipation. The condition appears sometimes to be a congenital defect. In some patients there may be constricting bands, or a congenital stricture.

Dietetic causes are more common. In sucklings it often arises from an unnatural dryness of the small residue which passes into the colon, and it may be very difficult to decide whether the fault is in the mother's milk or in the digestion of the child. Most probably it is in the latter, as some babies may be persistently costive on natural or artificial foods. Deficiency of fat in the milk is believed by some to be the cause. In children it is of the greatest importance that regular habits should be ensured. Carelessness on the

part of the mother in this matter often lays the foundation of troublesome constipation in after life. Impairment of the contractility of the intestine in consequence of inflammation, disturbance in the intestinal secretions, and deficiency in the defæcation reflex are the chief local causes.

Diagnosis.—Too often the statement of the patient is accepted without investigation. The diagnosis should include the cause of the constipation. It may be easy to overlook constipation. The patient may have a daily stool but of insufficient amount, or there may be marked retention of fæces with several loose stools daily due to irritation or the passage of fluid contents through the mass. There may be retention with a daily stool which is very hard. Many have wrong ideas as to a normal stool and it is an advantage to inspect the movements. In the recognition of the exact condition, an X-ray study is of the greatest value.

Treatment.—Much may be done by systematic habits, particularly in the young. The patient should go to stool at a fixed hour every day, whether there is desire or not, and the desire should always be granted. In adults the mental attitude is important. The need of the cultivation of regular habits is essential, but many patients are too careless and lazy to take sufficient trouble to insure this. Psycho-therapy has a very definite place in the therapy. Exercise in moderation is helpful, especially of the trunk and abdominal muscles. In stout persons and in women with pendulous abdomens the muscles should have the support of a bandage. Friction or massage is useful in the chronic cases. A good substitute is a metal ball weighing from four to six pounds, which may be rolled over the abdomen every morning for five or ten minutes. The function of the stomach should be thoroughly studied and any disturbance properly treated. The diet should be low in protein, with plenty of fruit and vegetables, particularly salads and tomatoes. It is often advisable to cut meat from the diet and substitute cereals, milk and milk foods. Oatmeal is usually laxative, though not to all; brown or bran bread is better than that made from fine white flour. A high-fat diet (200 grams of fat per day) is helpful in some patients. Fluids should be taken freely. A tumblerful of hot or cold water on rising, taken slowly, is efficacious in many cases. A glass of hot water at night may also be tried. A pipe or a cigar after breakfast is an aid for many men.

When the condition is not very obstinate it is well to try to relieve it by hygienic and dietetic measures. If drugs must be used they should be the milder saline laxatives, compound liquorice powder or senna leaves alone. Enemata are often necessary, and it is much preferable to employ them early than to constantly use purgative pills. Glycerine either in the form of suppository or as a small injection is valuable. Injections of tepid water, with or without soap, may be used with good effect. The patient should be in the dorsal position with the hips elevated, and it is best to let the fluid flow in slowly from a fountain syringe.

The usual remedies employed are often useless in spastic constipation. A very satisfactory measure is the olive or cotton seed oil injection. The patient lies on the back with the hips elevated, and from 15 to 20 ounces of oil are allowed to flow slowly (or are injected) into the bowel. The operation should take at least fifteen minutes. This may be repeated every day until the intestine is cleared, and subsequently a smaller injection every few days will

suffice. In the cases with a spastic colon the injection of oil at bedtime, which is retained during the night, is often effectual.

The ideal would be to manage constipation without the use of drugs but human nature being what it is we cannot hope for this. When drugs are used they should be as simple as possible. Mineral oil is often effectual, usually best taken about meal times. The combination with agar may be better and does not "leak" as often as the oil alone. Agar alone may be efficient. Castor oil is usually effectual (3 ss-i, 15-30 c. c.) and may be given in small doses (5 i, 4 c. c.) each night with benefit. Cascara, phenolphthalein, senna and some of the combinations of milder laxatives often do well. Magnesia is often useful. The persistent use of strong saline purgatives is to be condemned but small doses of mild salines may be effectual.

In children the indications should be met, as far as possible, by hygienic and dietetic measures. In the constipation of sucklings a change in the diet of the mother may be tried, or from one to three teaspoonfuls of cream may be given before each nursing. In artificially fed children the top milk with the cream should be used. Drinking of water, barley water, or oatmeal water will sometimes obviate the difficulty. If laxatives are required, simple syrup, manna, or olive oil may be sufficient. A conical piece of soap is sometimes efficacious. Massage along the colon may be tried. Small injections of cold water may be used. Large injections should be avoided, if possible. If it is necessary to give a laxative by the mouth, castor oil or fluid magnesia is the best. If there are signs of gastro-intestinal irritation, rhubarb and soda or gray powder may be given. In older children the diet should be carefully regulated.

VI. VISCEROPTOSIS

(*Splanchnoptosis, Enteroptosis, Glénard's Disease*)

Definition.—"Dropping of the viscera" is not a disease, but a symptom group characterized by looseness of the mesenteric and peritoneal attachments, so that the stomach, intestines, particularly the transverse colon, liver, kidneys, and spleen occupy an abnormally low position.

Symptoms and Signs.—There are two varieties: in one, which may be called constitutional or *congenital*, it is an expression of an anomaly of development, a narrow upper abdominal opening, low diaphragm and elongated visceral ligaments, all of which combined lead to a greater or less degree of prolapse of the abdominal viscera. The second, or *acquired visceroptosis*, is largely due to relaxation of the abdominal wall. The support of the viscera is due to the integrity of the reflex arc and abdominal muscles, the tonic action of which, as shown by the studies of Keith and of Sherrington, is brought into play by a reflex, the afferent end organs of which are the peritoneal nerves and Pacinian bodies.

In the first group is embraced a somewhat motley series of cases, in which, with a pronounced nervous or neurasthenic basis, there are displacements of the viscera *with symptoms*. The patients are usually young, more frequently women than men, and of spare habit. The condition may follow an acute illness with wasting. They complain, as a rule, of dyspepsia, throbbing in

the abdomen, and dragging pains or weakness in the back, and inability to perform the usual duties of life. A very considerable proportion of all the cases of neurasthenia present the local features of visceroptosis. When preparing for the examination one notices usually an erythematous flushing of the skin; the scratch of the nail is followed instantly by a line of hyperæmia, less often of pallor. The pulsation of the abdominal aorta is readily seen.

In the second group inspection of the abdomen shows a very relaxed abdominal wall, and, as a rule, the lineæ albicantes of recurring pregnancies. Peristalsis of the intestines may be seen, and in extreme cases the outlines of the stomach itself with its waves of peristalsis. On inflating the stomach the organ stands out with great prominence, and the lesser and greater curvatures are seen, the latter perhaps well below the navel. The waves of peristalsis are feeble and without the force of those seen in the stomach dilated from stricture of the pylorus. The condition of descensus ventriculi with atony is best studied in this group of cases. An important point to remember is that it may exist in an extreme grade without symptoms.

Radiography has given much information of the position of the viscera. The stomach may be vertically placed and reach far below the navel; its motility may be normal, but there may be stasis from associated pyloric spasm or from kinking of the duodenum. Clapotage or splashing is usually distinct.

There is usually much relaxation of the mesentery and of the peritoneal folds which support the intestines. The colon is displaced downward (coloptosis), with consequent kinking at the flexures. The descent may be so low that the transverse colon is at the brim of or even in the pelvis. It may indeed be fixed or bent in the form of a V. It is frequently to be felt as a firm cord crossing the abdomen at or below the level of the navel. This kinking may take place not only in the colon but at the pylorus, where the duodenum passes into the jejunum, and where the ileum enters the cæcum.

The cæcum may be very movable and with this there may be pain, attacks of colic and constipation. There may be fullness in the cæcal region and on palpation the distended cæcum is easily felt. The mass may be very movable. Incompetence of the ileo-cæcal valve may exist. It is often difficult to know how much significance belongs to this condition. It is undoubtedly present in many healthy persons and frequently with an abnormally movable cæcum. In others it seems to be associated with a variety of abdominal symptoms, often associated with intestinal stasis. The X-ray study is important in the diagnosis of the ileo-cæcal incompetency and any associated conditions.

Nephroptosis, or displacement of the kidney, is one of the most constant phenomena in visceroptosis. It is well to distinguish between the kidney which one can just touch on deep inspiration—palpable kidney—one which is freely movable, and on deep inspiration descends so that one can put the fingers of the palpating hand above it and hold it down, and, thirdly, a floating kidney, which is entirely outside the costal arch, is easily grasped in the hand, readily moved to the middle line, and low down toward the right iliac fossa. Some hold that the designation floating kidney should be restricted to the cases in which there is a meso-nephron, but this is excessively rare, while extreme grades of renal mobility are common. Some of the more serious sequences of movable kidney, namely, Dietl's crises and intermittent hydro-nephrosis, will be considered with diseases of the kidney.

Displacement of the *liver* is very much less common. In thin women who have laced, the organ is often tilted forward, so that a large surface of the lobes comes in contact with the abdominal wall; it is a very common mistake under these circumstances to think that the organ is enlarged. Dislocation of the liver itself will be considered later.

Mobility of the *spleen* is sometimes very marked. In an extreme grade it may be found in almost any region of the abdomen and may be mistaken for a fibroid or ovarian tumor. A considerable proportion of the cases come first under the care of the gynaecologist.

The explanation of the phenomena accompanying visceroptosis is by no means easy. It has been suggested by Glénard and others that overfilling of the splanchnic vessels in consequence of displacement accounts for the feelings of exhaustion and general nervousness. Many patients carry themselves badly, with resulting muscular strain, and this sometimes accounts for the pain in the back. In a large proportion of the cases no symptoms occur until after an illness or some protracted nervous strain.

Treatment.—In a majority of all cases four indications are present: To treat the existing neurasthenia, to relieve the nervous dyspepsia, to overcome the constipation, and to afford mechanical support to the organs. Three of these are considered under their appropriate sections. In cases in which enteroptosis has followed loss in weight after an acute illness or worries and cares an important indication is to fatten the patient.

A well-adapted abdominal support is one of the most important measures in enteroptosis. In many of the milder grades it alone suffices. There is no single simple measure which affords relief to distressing symptoms in so many cases as the abdominal bandage. It should fit the lower abdomen snugly, and be arranged with straps so that it can not ride up over the hips. A special form must be used for movable kidney. In some cases support may be given by the use of adhesive strapping. Exercises to strengthen the abdominal muscles and proper abdominal breathing are aids. General "setting-up" exercises are often helpful. The patients should rest and lie on the right side as much as possible; an hour's rest after meals is useful. Some are aided by having the foot of the bed elevated. Some of the more aggravated types of enteroptosis are combined with such features of neurasthenia that a rigid Weir Mitchell treatment is indicated. In a few very refractory cases surgical interference may be called for. With incompetency of the ileo-cæcal valve general measures to relieve stasis are indicated and if not successful operation may be advisable.

And, lastly, the physician must be careful in dealing with the subjects of visceroptosis not to lay too much stress on the disorder. It is well never to tell the patient that a kidney is movable; the symptoms may date from a knowledge of the existence of the condition.

VII. NEOPLASM OF THE INTESTINE

New growth of the bowel occurs almost entirely in the colon; involvement of the small bowel is very rare. The majority of growths occur in the rectum or sigmoid. The age is usually between 40 and 60. The form is a colum-

nar-celled carcinoma and a striking feature is the late occurrence of metastases.

Symptoms.—In the early stages these are generally indefinite and consist in abdominal discomfort, usually in the lower part, and constipation in one whose bowels have been regular or aggravation of existing constipation. Occasionally diarrhoea occurs as an early feature, due to irritation from a growth which does not cause narrowing, or from retained fæces. The constipation increases; ribbon-shaped or round small stools occur at times but are not distinctive. There is mucus in the stools and pus and blood (often occult) if ulceration results. The discomfort increases to pain which may be colicky and, as there is obstruction visible, peristalsis may be present. The features of obstruction gradually increase and at this stage a tumor may be felt by rectal or abdominal examination—occasionally a tumor is felt when there are no signs of obstruction. The tumor is usually hard, rarely painful and often movable. General features, emaciation, anæmia, and cachexia, as a rule, come on slowly and late in the course. Peritonitis may result from perforation.

Diagnosis.—Disturbance of the bowels in a person over forty, without evident explanation, demands the consideration of new growth. The X-ray study is of great value but only if there is obstruction. A study of the stools and a rectal examination with the finger and tube should always be made. The treatment is surgical. The harm done by the careless giving of purgatives for constipation without a proper diagnosis of the cause is well illustrated in neoplasm of the bowel.

VIII. MISCELLANEOUS AFFECTIONS

I. MUCOUS COLITIS

Known by various names, such as *membranous enteritis*, *tubular diarrhoea*, *mucous colic*, and *myxoneurosis intestinalis*, this remarkable disease has been recognized for several centuries. Spasticity of the colon is often associated with it; both represent disturbance of the sympathetic nervous system. The passage of mucus in large quantities from the bowel is met with, first, in catarrh of the intestine, due to various causes. It is not uncommon in children, and may be associated with disturbances of digestion and slight colic. Secondly, in local disease or irritation of the bowel, in cancer of the colon and of the rectum. In tubo-ovarian disease much mucus and slime may be passed. Thirdly, true mucous colitis, a *secretion neurosis* of the large intestine met with particularly in nervous and hysterical patients. It is more common in women and has increased greatly of late years. Some cases appear to be due to food allergy. There is an abnormal secretion of a tenacious mucus, which may be slimy and gelatinous, like frog-spawn, or it is passed in strings or strips, more rarely as a continuous tubular membrane. The membrane *in situ* adheres closely to the mucosa, but is capable of separation without any lesion of the surface. Microscopically the casts are mucoid, of a uniform granular ground substance through which there are remnants of cells, some of which have undergone hyaline transformation. Triple phos-

phate, cholesterin, and fatty crystals are present, and occasionally fine, sand-like concretions. The epithelium of the mucosa seems to be intact.

Symptoms.—In a large proportion of all the cases the subjects are nervous in greater or less degree. Some cases have had hysterical outbreaks, and there may be hypochondriasis or melancholia. The patients are self-centred and often much worried about the mucous stools. Some of the cases are among the most distressing with which we have to deal, invalids of many years' standing, neurasthenic to an extreme degree, with recurring attacks of pain and the passage of large quantities of mucus or even intestinal casts.

In many cases the attacks come on in paroxysms, associated with colicky pains, or occasionally crises of the greatest severity, so that appendicitis may be suspected. Emotional disturbances, worry of all sorts, or an error in diet may bring on an attack. Constipation is a special feature in many cases. Sometimes there are attacks of nervous diarrhoea. Some patients have a movement after each meal. This is due to an active gastro-colic reflex, so that faeces reach the rectum after each meal.

While the disease is obstinate and distressing, it is rarely serious, though Herringham states that he knew of three cases of mucous colitis in which death occurred suddenly, in all with great pain in the left side of the abdomen. The abdomen itself is rarely distended. There is often a painful spot between the navel and the left costal border, tender on pressure, and sometimes the paroxysms of pain seem centred in this region. A spastic condition of the colon frequently exists and is easily recognized by palpation.

Diagnosis.—This is rarely doubtful, but it is important not to mistake the ^{Stool} membranes for other substances; thus, the external cuticle of asparagus and undigested portions of meat or sausage-skins sometimes assume forms not unlike mucous casts, but microscopic examination will quickly differentiate them. The presence of ulcers, polypi and neoplasm should be excluded. Mucous colitis with severe pain may be mistaken for appendicitis.

Treatment.—The mechanism of the condition should be carefully explained to the patient. An important point is to avoid fatigue, physical, emotional or nervous. Particular care should be taken to overcome constipation. Drugs are not of much value, but if there is marked spasm, bromide and belladonna may be useful. It is quite useless to give bismuth and so-called intestinal remedies. First the basic neurasthenic state is to be dealt with, and this may suffice for a cure. Secondly, daily irrigations of the colon—one to two pints of warm alkaline fluid. The injection of olive oil at bedtime is sometimes helpful; it should be retained during the night. Thirdly, the coarser sorts of food which leave a large residue should be eaten.

II. DILATATION OF THE COLON

There are four groups of cases. In the first the distention is entirely gaseous, and occurs not infrequently as a transient condition. In many cases it has an important influence, inasmuch as it may be extreme, pushing up the diaphragm and seriously impairing the action of the heart and lungs. It is an occasional cause of sudden heart-failure. In pneumonia and other acute diseases this distention may be extreme.

In the second group are the cases in which the distention of the colon

is caused by solid substances, as faecal matter. In institutions, particularly for the insane, it is not infrequent to find the aged with great distention.

When, thirdly, the dilatation is due to an organic obstruction the colon may reach a very large size. These cases are common enough in malignant tumors and sometimes in volvulus. Dilatation of the sigmoid flexure occurs particularly when this portion of the bowel is congenitally very long. In such cases the bowel may be so distended that it occupies the greater part of the abdomen, pushing up the liver and the diaphragm. An acute condition is sometimes caused by a twist in the meso-colon. And, fourthly—

aloud Idiopathic Dilatation.—Hirschprung's disease. The cases are not uncommon, occurring in children and in young adults. The sigmoid flexure alone or the entire colon is involved, and the size may be colossal. In Formad's case the circumference of the colon was from fifteen to thirty inches, and the weight of the contents forty-seven pounds. There is a congenital anomaly (muscular hyperplasia) with disturbance of the neuromuscular mechanism which involves a varying amount of the colon and may involve the rectum. The changes may be local. There may be a failure to relax at the pelvirectal or anal sphincter. The symptoms are very definite—constipation, an enlarged abdomen, attacks of pain with increasing distention, and then diarrhoea, either natural or induced, with relief. Such attacks may occur from birth and continue to the twentieth or thirtieth year. The abdominal picture is distinctive—the great enlargement of the upper half of the abdomen, the spreading of the costal arch, the remarkable length from the ensiform cartilage to the navel, and in the attacks the coils of the colon stand out prominently, and even the longitudinal bands may be seen.

The outlook is uncertain. Stretching of the pelvirectal sphincter may be useful. Every effort should be made to empty the bowel by irrigations. As a rule, it is a progressive malady for which surgery alone offers complete relief. Resection of the enlarged colon has been done in a good many cases. Colotomy and colostomy have been successful. Ramisectomy on the left side has been successful.

III. INTESTINAL SAND

“Sable Intestinal.”—There are two groups of cases in which sand-like material is passed with the stools. The false, in which it is made up of the remains of vegetable food and fruits which have resisted digestion or which have become encrusted with earthy salts. True intestinal sand of animal origin, gritty fine particles, usually gray, black or brown, is formed in the bowel and is made up largely of lime salts. In mucous colitis this material may be passed at intervals for months. In treatment the saturated fats, as in meat, cream and butter, should be left out of the diet; olive oil may be used instead. The usual management of mucous colitis is indicated.

IV. DIVERTICULITIS—PERISIGMOIDITIS

Congenital diverticula, of which Meckel's is the type, may cause strangulation or obstruction.

Acquired diverticula, commonly hernial protrusion of the mucous and

serous coats, occur anywhere in the intestinal tract. In the small bowel they rarely cause symptoms. They may occur throughout the colon but are most frequent in the sigmoid. This is termed diverticulosis. The diverticula may become the seat of inflammation—diverticulitis. There is usually constipation of long standing with discomfort or pain in the lower left abdomen. Telling and Gruner analyzed 324 cases; 68 per cent. were males. The evaginations of the mucosa are usually the result of high intra-colic pressure with gas or feces in the aged, associated with constipation.

The secondary pathological processes are mechanical, as torsion, formation of concretions and lodgment of foreign bodies; and inflammatory, acute diverticulitis, which may rapidly become gangrenous; chronic inflammation leading to thickening, and tumor formation and narrowing; perforation, causing local abscess, general peritonitis or fistula. Other changes are chronic local peritonitis with adhesions, metastatic suppuration, and in late stages cancer may develop. Adhesions may form with the bladder with a resulting vesico-colic fistula.

The symptoms may not permit of more than a tentative diagnosis. Pain in the left lower quadrant with tenderness, rigidity and a mass in a person over sixty, who has been constipated, should suggest diverticulitis as well as cancer. The usual absence of blood in the stools, the long history of pain in the lower left quadrant, tumor formation and perhaps later disappearance, negative sigmoidoscopy, slight fever and good nutrition or even obesity are in favor of the former. Severe intestinal hæmorrhage may occur. The X-ray study is of value. The stools should be kept soft and oil enemas used when necessary. Operation may be required for acute conditions.

V. AFFECTIONS OF THE MESENTERY

Hæmorrhage (*Hæmatoma*).—Instances in which the bleeding is confined to the mesenteric tissues are rare; more commonly the condition is associated with hæmorrhagic infiltration of the pancreas and with retroperitoneal hæmorrhage. It occurs in rupture of aneurisms, either of the abdominal aorta or of the superior mesenteric artery, in malignant forms of the infectious fevers, small-pox, and in individuals in whom no predisposing conditions exist.

Affections of the Mesenteric Vessels.—(a) **ANEURISM** (see page 878).

(b) **EMBOLISM AND THROMBOSIS.**—*Infarction of the Bowel.*—When the mesenteric vessels are blocked by emboli or thrombi the condition of infarction follows in the territory supplied, which may pass on to gangrene or to perforation and peritonitis. If the superior mesenteric artery is blocked the result is fatal. In the veins the thrombosis may be primary, following infective processes in the intestines, particularly about the appendix, or it occurs in cachectic states. Secondary thrombosis is met with in cirrhosis of the liver, syphilis, and pylephlebitis, or may result from the stasis caused by arterial emboli. There are two groups—acute and chronic. In the former the onset is sudden with violent paroxysmal abdominal pain, not specially localized, persistent vomiting which usually lessens after some hours, and bloody stools. The abdomen may be slightly full but there is no muscle spasm; the percussion note is dull. There may be slight fever or the temperature is

Anal
to
appendicitis

normal or sub-normal. The signs of shock and collapse are usually marked. Signs of peritonitis may appear later. Death may occur in a few hours. In the chronic cases the onset is insidious; there may be vague abdominal discomfort without localized tenderness. The diagnosis is extremely difficult, and the acute cases are usually regarded as obstruction. The occurrence of severe pain without rigidity of the abdominal walls is suggestive. Operation has been done with recovery in a few cases. In J. W. Elliot's successful case 48 inches of the bowel were resected. In the horse, infarction of the intestine, commonly in connection with the verminous aneurisms of the mesenteric arteries, is the usual cause of colic.

Diseases of the Mesenteric Veins.—Dilatation and sclerosis occur in cirrhosis of the liver. In prolonged obstruction there may be large saccular dilatations with calcification of the intima, as in a case of obliteration of the venæ portæ described by the senior author. Suppuration of the mesenteric veins is not rare, usually with pyelephlebitis. The mesentery may be much swollen and is like a bag of pus; only by careful dissection one sees that the pus is within channels representing dilated mesenteric veins.

Disorders of the Chyle Vessels.—Varicose, cavernous, and cystic chylangiomas are met with in the mucosa and submucosa of the small intestine, occasionally of the stomach. Extravasation of chyle into the mesenteric tissue is sometimes seen. Chylous cysts may occur at the root of the mesentery. Bramann records a case in a man aged sixty-three, in which a cyst of this kind the size of a child's head was healed by operation. There is an instance of a congenital malformation of the thoracic duct, in which the receptaculum formed a flattened cyst which discharged into the peritoneum, and a chylous ascitic fluid was withdrawn on several occasions. Homans reported the case of a girl who, from the third to the thirteenth year, had an enlarged abdomen. Laparotomy showed a series of cysts containing clear fluid, supposed to be dilated lymph vessels connected with the intestines.

Cysts of the Mesentery.—They may be either dermoid, hydatid, serous, sanguineous, or chylous. They occur at any portion of the mesentery, and range from a few inches in diameter to large masses occupying the entire abdomen. They are frequently adherent to the neighboring organs, to the liver, spleen, uterus, and sigmoid flexure.

The symptoms usually are those of a progressively enlarging tumor in the abdomen. Sometimes a mass develops rapidly, particularly in the hæmorrhagic forms. Colic and constipation or acute obstruction are present in some cases. The general health, as a rule, is well maintained in spite of the progressive enlargement of the abdomen, which is most prominent in the umbilical region. Mesenteric cysts may persist for many years.

The diagnosis is extremely uncertain, and no single feature is in any way distinctive. The important signs are: the great mobility, the situation in the middle line, and the zone of tympany in front of the tumor. Of these, the second is the only one which is at all constant, as when the tumors are large the mobility disappears, and at this stage the intestines, too, are pushed to one side. It is most frequently mistaken for ovarian tumor. Movable kidney, hydronephrosis, and cysts of the omentum have also been confused with it. The only treatment is surgical.

VI. AFFECTIONS OF THE DUODENUM

Dilatation is often associated with visceroptosis and compression of the terminal portion of the duodenum by the root of the mesentery. Adhesions from local peritonitis are responsible in some cases. The symptoms are (1) pain in the upper abdomen, sometimes described as a pulling or dragging sensation, sometimes more severe, and suggesting ulcer or gall-bladder disease; (2) vomiting which is frequent and sometimes persistent; (3) constipation; and (4) marked vagotonic features. The X-ray study is an important aid in the diagnosis. In treatment, position may be useful, the patient lying on the face with the feet elevated, or on the left side, or taking the knee-chest position. Correction of the visceroptosis may give relief. In severe cases surgical intervention is advisable.

Duodenal adhesions may simulate ulcer very closely and in the X-ray study it may not be possible to distinguish them. The symptoms are not distinctive and suggest ulcer or gall-bladder disease. They often occur intermittently, which suggests that another factor is present. Treatment is difficult; symptomatic medical treatment should be given; surgery is not always successful. Diverticula, chronic distention, stenosis, duodenal stasis, and reverse peristalsis may give a variety of symptoms. Their recognition depends largely on the results of the X-ray study.

Fixation.—There may be bands passing from the gall-bladder to the colon which surround the duodenum or are in front of it. By these the duodenum is held high. The onset of symptoms is usually between sixteen and twenty years of age but may be in childhood. There is often pain, which may occur in attacks, with distress and distention from one-half to an hour after meals. The attacks of pain may simulate cholecystitis. The stomach may be dilated and its contents usually show a high acidity. As the patient grows older, headache and weakness with vasomotor and nervous symptoms become prominent. Constipation is common. The diagnosis is made by the X-ray study and usually better by fluoroscopy than by plates. The apex of the duodenum is sharp and held up to the right, looking as if suspended on a hook and making a sharp turn. The duodenum beyond the fixed point may be against the liver and flat. The treatment is surgical.

H. DISEASES OF THE LIVER

I. JAUNDICE

Definition.—Jaundice or icterus is a condition characterized by coloration of the skin, mucous membranes, and fluids of the body by bile-pigment. It is a symptom, not a disease, and is met with in a variety of conditions. In carotinæmia there is a yellow discoloration of the skin but the sclerotics are not involved. The blood serum and urine are colored owing to the presence of carotin, derived from foods rich in it (carrots, spinach, egg yolk, etc.).

There is difference of opinion as to whether jaundice can occur without the action of the liver cells. Bilirubin may be formed in tissues or serous

cavities from extravasated blood; this however is apparently not absorbed. Great importance attaches to the "reticulo-endothelial" systems, the cells of which occur in various parts of the body. The chief interest with regard to jaundice belongs to those in the liver (cells of Kupffer), which lie along the venous capillaries, and those lining the sinuses of the spleen. There are also some in the bone marrow. It is suggested that these cells are concerned in the production of hæmolytic jaundice and not the cells of the liver. The cells of the reticulo-endothelial system break down hæmoglobin and manufacture bilirubin or its precursor and the liver cells pass it into the bile capillaries. The bile capillary begins with a blind end and is surrounded by the glandular cells. Between the glands are the capillaries passing from the portal system to the branch of the hepatic vein in the centre of the lobule. The Kupffer cells lie along the walls of the capillaries.

One theory of bilirubin formation is that the polygonal glandular cells of the liver are chiefly concerned in the transference of the bile pigment from the blood capillaries to the bile capillaries. In this passage the bilirubin is altered and so there are two varieties of bilirubin, one which has passed through the liver cells (giving the direct immediate reaction of van den Bergh) and one which has not done so and passes into the blood (indirect delayed reaction).

McNee suggests the following possibilities in the causation of jaundice: (1) Bile pigment passes through the polygonal cells to reach the bile capillaries but is obstructed and reabsorbed into the blood. (2) The polygonal cells are damaged; all or part of the bile pigment is unable to enter them and passes into the circulation by the hepatic veins. (3) With excessive blood destruction there may be too much bilirubin for the polygonal cells to handle. Some passes into the bile capillaries, coloring the stools, and the remainder into the circulation. (4) Damage of the polygonal cells and obstruction in the bile ducts.

By the van den Bergh test small amounts of bilirubin can be detected in the blood and measured quantitatively. Bilirubin may be present in the blood in increased amounts without clinical jaundice (latent jaundice). Normal serum contains bilirubin which gives the indirect or delayed reaction, sometimes called "functional bilirubin," in amounts of 0.2-0.5 of the van den Bergh unit (1-1,000,000 to 1-400,000). Of the two forms of bilirubin, one is found usually in obstructive jaundice and the other in hæmolytic jaundice. These correspond to the two reactions given by the van den Bergh test. In obstructive jaundice the reaction is direct or immediate; the bilirubin has passed through the polygonal cells and then been absorbed. In hæmolytic jaundice the reaction is indirect or delayed; the bilirubin has been formed independently of the liver cells and has not passed through them. In toxic and infective jaundice the reaction is biphasic, possibly due to both forms of bilirubin being present. In some cases two or three of the varieties of jaundice may be combined. The amount of bilirubin in the blood may be increased before jaundice is evident.

Dissociated Jaundice.—In this the bile pigment and bile salts behave differently; one may be retained or reabsorbed while the other is excreted normally. Retention of pigment with excretion of bile salts is common in the late stages of catarrhal jaundice and the reverse in some cases of cirrhosis of

the liver. Occasionally the kidneys apparently excrete bile salts but not bile pigment.

I. OBSTRUCTIVE HEPATIC JAUNDICE

The chief causes of obstructive jaundice are: (1) Obstruction by foreign bodies within the ducts, as gall-stones and parasites; (2) by inflammatory tumefaction of the duodenum or of the lining membrane of the duct; (3) by stricture or obliteration of the duct; (4) by tumors closing the orifice of the duct or growing in its interior; (5) by pressure on the duct from without, as by tumors of the liver itself, of the stomach, pancreas, kidney, or omentum; by pressure of enlarged glands in the fissures of the liver, and, more rarely, of abdominal aneurism, fecal accumulation, or the pregnant uterus. There are probably factors additional to the obstruction itself. There may be obstruction from cholangitis and also damage to the hepatic cells. Biliary thrombi in the bile capillaries are formed in some cases, possibly due to abnormal bile.

Under obstructive jaundice may perhaps be placed the cases of jaundice from mental shock or depressed emotions, which "may conceivably cause spasm and reversed peristalsis of the bile-duct" (W. Hunter).

Symptoms.—(a) *Icterus, or Tinting of the Skin and Conjunctivæ.*—The color ranges from a lemon-yellow to a deep olive-green or bronzed hue in permanent obstruction. In some instances the color of the skin is greenish black, the so-called "black jaundice." The color of the skin is no certain indication of the amount of bilirubin in the blood. Except the central nervous system, all of the tissues are stained.

(8)
Icterus

(b) In the more chronic forms pruritus is a most distressing symptom. There may be a curious pre-icteric itching. Sweating is common, and may be curiously localized to the abdomen or to the palms of the hands. Lichen, urticaria, and boils may occur. Xanthoma multiplex is rare. Usually in the flat form, rarely nodular, they are most common in the eyelids and on the hands and feet but may be numerous over the whole body and occasionally they are found in the bile ducts. The patches contain cholesterol. After persisting for years they may disappear. In very chronic cases telangiectases develop in the skin, sometimes in large numbers over the body and face, occasionally on the mucous membrane of the tongue and lips, forming patches of a bright red color from 1 to 2 cm. in breadth.

Pruritus

(c) The blood serum is tinged with bilirubin. With the van den Bergh test an immediate direct reaction is obtained. Figures of 50 units (1-4,000) have been found. At least four units (1-50,000) must be present before bile passes into the urine. This reaction is of aid in the diagnosis of obstructive from hæmolytic jaundice.

Bl. serum
tinged

(d) The secretions are colored with bile-pigment. The sweat tinges the linen; the tears, saliva and milk are rarely stained. The expectoration is not often tinted unless there is inflammation, as in pneumonia. The urine may contain the pigment before it is apparent in the conjunctiva. The color varies from light greenish yellow to a deep black-green. In jaundice of long standing or great intensity the urine usually contains albumin and always bile-stained casts.

Secrets
tinged

(e) No bile passes into the intestine. The stools are of a pale drab or

Stool

slate-gray color, and usually fetid and pasty. The "clay-color" of the stools is also in part due to undigested fat which, according to Müller, may be increased from the normal 7 to 10 per cent. to 55 or 78.5 per cent. There may be constipation; in many instances, owing to decomposition, there is diarrhoea.

(f) Slow Pulse.—The heart's action may fall to 40, 30, or even to 20 per minute. It is particularly noticeable in the cases of catarrhal and recent jaundice, and is not as a rule an unfavorable symptom. It occurs only in the early stages of jaundice. The respirations may fall to 10 or even to 7 per minute. Xanthopsia, or yellow vision, may occur.

(g) Hæmorrhage.—The tendency to bleeding in chronic icterus is a serious feature and in some cases the blood coagulation time is much retarded. This is an important point as uncontrollable hæmorrhage is a well-recognized accident in operating upon patients with chronic jaundice. Purpura, large subcutaneous extravasations, more rarely hæmorrhages from the mucous membranes, occur in protracted jaundice, and in the more severe forms.

(h) Cerebral Symptoms.—Irritability, great depression of spirits, or even melancholia may be present. In any case of persistent jaundice special nervous phenomena may develop and rapidly prove fatal—such as sudden coma, acute delirium, or convulsions. Usually the patient has a rapid pulse, slight fever, and a dry tongue, and he passes into the so-called "typhoid state." These features are not nearly so common in obstructive as in febrile jaundice, but they not infrequently terminate a chronic icterus in whatever way produced. The group of symptoms has been termed *cholæmia*, or, on the supposition that cholesterin is the poison, *cholesteræmia*; but its true nature has not been determined. In some cases the symptoms may be due to uræmia.

II. TOXIC AND INFECTIVE HEPATIC JAUNDICE

This is the commonest form of jaundice and probably the mechanism varies in different cases depending on the relative extent of injury to the liver cells and obstruction. The latter is due to cholangitis with inflammatory changes in the bile capillaries and ducts. The results of the functional tests prove the presence of damage of the hepatic cells. There may be many grades of damage ranging from cloudy swelling (as in typhoid fever), to fatty degeneration (chloroform poisoning) or to marked necrosis (acute yellow atrophy). In the detoxicating function of the liver cells there is abundant opportunity for damage. The van den Bergh test is of little clinical value in this form, the reaction being *biphasic*, due possibly to the two varieties of bilirubin being present. The relative amounts may vary. "The absorbed bile in toxæmic jaundice is usually rich in bile pigments which arise from the increased destruction of hæmoglobin; it is deficient in bile salts owing to the impaired function of the liver cells" (Willcox). The mucous membrane of the duodenum may be swollen and show hæmorrhages.

The main causes may be grouped as follows:

- (1) Infectious diseases, as typhoid fever, pneumonia, yellow fever, syphilis, etc.
- (2) Chemical poisons, as chloroform, arsenobenzol derivatives, tetrachlor-methane, inorganic arsenic compounds, phosphorus, etc.
- (3) Certain toxic conditions, as acute yellow atrophy and uræmia.

(4) In conditions, probably of infective nature, termed infectious, febrile or malignant jaundice.

The symptoms are not nearly so striking as in the obstructive variety. Bile is present in the stools and the skin has in many cases only a slight lemon tint. The urine may contain no bile-pigment, but the urinary pigments are considerably increased. In the severer forms, as in acute yellow atrophy, the color may be more intense. The constitutional disturbance may be very profound, with high fever, delirium, convulsions, suppression of urine, black vomit, and cutaneous hæmorrhages. The toxæmia may take the form of stupor or coma.

Certain special forms deserve notice.

Tetrachlorethane.—The vapor inhaled in the coating of aeroplane wings is a cause of illness. Headache, nausea, and abdominal discomfort may be present for a week or more before jaundice appears. If quickly removed from the influence of the vapor, recovery is prompt, but icterus gravis may occur with purpura, convulsions, suppression of urine and coma. Fever is absent and there is no anæmia, and the jaundice is unusually deep. There is extensive degeneration of the liver cells, and if the disease lasts many weeks, a "replacement cirrhosis." Contraction of the liver with ascites may follow.

Trinitrotoluene.—Many munition workers suffered severely, some from the local effects, dermatitis or erythema, many more from inhalation of the dust or swallowing the powder. The toxic symptoms come on after a variable period of exposure from a few days to months. Nausea, weakness and pallor, with signs of irritation of the throat are early symptoms. Then jaundice begins, and if severe, there are the usual toxic features. The anæmia resembles the pernicious type, with a high color index and leucopenia. At first enlarged, the liver may subsequently shrink, and some of the cases have the picture of acute yellow atrophy with purpura and hæmorrhages. In both these forms when jaundice is severe, full alkaline treatment is helpful—sodium citrate and sodium bicarbonate, 30 grain (2 gm.) doses of each every two or three hours and intravenous injection of normal saline with two drams (8 gm.) of bicarbonate of soda to the pint (Willcox). Dinitrophenol, dinitrobenzene and picric acid may cause toxic jaundice.

Arsenobenzol Derivatives.—Occasional fever with nausea, irritation of the skin and scattered purpura may follow a full dose of arsphenamine. The severer symptoms usually come on in two or three days with fever, delirium, jaundice and death in coma or with convulsions. They are especially likely to occur if there is any hepatic disease. Purpura may be very extensive with hæmorrhage from the mucous membranes. Death has followed within two days. The liver presents widespread necroses with fatty degeneration. In case of recovery the size of the liver may be greatly reduced.

III. HÆMOLYTIC JAUNDICE

In this form the evidence suggests that bilirubin is formed outside the liver, apart from the hepatic cells, and in this the reticulo-endothelial system, especially in the spleen, assumes great importance. With increased blood destruction the cells of the reticulo-endothelial system, especially of the spleen, become over-active with a resulting increased formation of bilirubin. The

bilirubin formed in this way differs from that which has passed through the hepatic cells. The van den Bergh test gives the *delayed indirect* reaction, the same as given by the bile pigment normally in the blood. The absence of bile pigment from the urine and its presence in the fæces (acholuric jaundice) is important. The excretion of bilirubin by the kidney in hæmolytic jaundice is different from that in obstructive jaundice and bile rarely, if ever, passes through the kidney in the hæmolytic form. It may be excreted as urobilin. Biliary thrombi are often found in the bile capillaries. The importance of the spleen in hæmolytic jaundice is proved by the cases of acholuric jaundice in which removal of the spleen results in the disappearance of the jaundice. In pernicious anæmia the bilirubin content of the blood is always increased, usually to 3-5 units.

The *diagnosis* of hæmolytic jaundice is greatly aided by the van den Bergh reaction. Many cases of *latent jaundice* (in which there is retention of bile pigment without coloration of the skin or bile in the urine) belong here, and in these this reaction is essential in diagnosis.

IV. HEREDITARY JAUNDICE

A family form of icterus has long been known and there are several groups. First, *icterus neonatorum*, as in the remarkable instance described by Glaister (Lancet, March, 1879), in which a woman had eight children, six of whom died of jaundice shortly after birth; one had stenosis of the common duct, which, as John Thomson has shown, is, with angiocholitis, a common lesion in this affection. Still more remarkable is it that the mother of this woman had twelve children, all of whom were icteric after birth, but the jaundice gradually disappeared. A brother of the woman had several children who also were jaundiced at birth. Glaister states that all of the children of Morgagni, fifteen in number, had icterus neonatorum.

Secondly, the *acholuric* or *chronic splenomegalic hæmolytic jaundice*, which may be hereditary or familial or sometimes acquired late in life. The red cells are fragile and easily hæmolyzed with liberation of hæmoglobin and an excess of bilirubin formed in the spleen. There is no obstruction. The jaundice is usually slight and varies from time to time. The fæces are normal in color; the urine is free from bile. The red cells are very fragile and undergo hæmolysis in 0.6 to 0.42 per cent. sodium chloride solution (the normal is 0.42 to 0.34 per cent. solution). Moderate secondary anæmia is common. The spleen is enlarged but the liver is normal. In the acquired form the jaundice is less prominent but the anæmia is more marked and may suggest the pernicious form. There may be a leucocytosis with myelocytes and an increase in eosinophiles. There is a positive indirect reaction with the van den Bergh test. In diagnosis the increased fragility of the red cells is characteristic with the other features. *Treatment* consists in removal of the spleen if possible and symptomatic measures.

Thirdly, a group of cases with enlargement of the spleen and liver and marked constitutional disturbances, anæmia, dwarfing of stature, infantilism, and slight jaundice. Cases which have been described as Hanot's cirrhosis have occurred in two or three members of a family, and the jaundice has dated from early childhood.

Diagnosis of Jaundice.—Clinical jaundice is usually easily recognized in daylight by the discoloration of the sclerotics; in artificial light slight grades are not seen. Yellow fat in the sclerotics and the pigmentation in negroes may give difficulty. If any doubt exists and in all cases of latent jaundice the van den Bergh test is positive. Amounts of 4 units are necessary in obstructive jaundice to cause surface pigmentation; in hæmolytic jaundice larger amounts may be present without surface pigmentation. In the diagnosis of the form of jaundice the whole picture must be studied; the van den Bergh test is of great value but is not infallible and there are some puzzling exceptions to the general rules. The recognition of latent jaundice may suggest an early stage of carcinoma of the liver or of failure of cardiac compensation.

Treatment.—This is essentially that of the causal condition but the irritation caused by the jaundice often demands relief. Warm alkaline baths, sponging the skin with a solution of sodium bicarbonate or phenol (1-2 per cent.) or the application of 5 per cent. menthol ointment may give relief. It is well to reduce the fats in the diet. The administration of calcium salts or the injection of blood serum is advisable before operation.

II. ICTERUS NEONATORUM

New-born infants are liable to jaundice, which in some instances rapidly proves fatal. A mild and severe form may be recognized.

The *mild or physiological icterus* of the new-born is common in foundling hospitals, and not very infrequent in private practice. In 900 consecutive births at the Sloane Maternity icterus was noted in 300 cases (Holt). The jaundice appears early, usually on the first or second day, and is of moderate intensity. The urine may be bile-stained and the feces colorless. The nutrition of the child is not usually disturbed, and in the majority the jaundice disappears within two weeks. This form is never fatal. The bilirubin content of the blood is often increased at birth and the van den Bergh reaction is the delayed indirect one suggesting that the jaundice is hæmolytic and not obstructive. ?

The *severe form* of icterus in the new-born may depend upon (a) congenital absence of the common or hepatic duct, of which many instances are on record; (b) congenital syphilitic hepatitis; and (c) septic infection, associated with phlebitis of the umbilical vein. This is a severe and fatal form, in which hæmorrhage from the cord may also occur.

Curiously enough, in contradistinction to other forms, the brain and cord may be stained yellow in icterus neonatorum, sometimes diffusely, more rarely in definite foci corresponding to the ganglion cells which have become deeply stained (Schmorl).

III. ACUTE YELLOW ATROPHY

(*Malignant Jaundice; Icterus gravis: Acute Necrosis*)

Definition.—An acute widespread autolytic necrosis of the liver cells, probably due to various causes, characterized by jaundice, toxæmia and a reduction in the volume of the liver. It is a symptom-complex rather than a disease.

Etiology.—The first authentic account was given by the famous old Paris doctor—Ballonius—sometimes called the French Hippocrates (1538-1616). Bright gave a good description in 1836. It is a rare disease, as among 28,000 medical cases admitted to the Johns Hopkins Hospital in nearly twenty-three years there were only 3 cases. It varies in frequency in different countries, and seems to be rarer in the United States than in Germany and England. The majority of cases occur between the tenth and the fortieth year. Rolleston collected 42 cases occurring within the first ten years of life.

Acute necrosis of the liver occurs under many conditions: (a) In the infections, syphilis, typhoid fever, diphtheria and septicæmia. (b) Non-bacterial poisons. The delayed chloroform poisoning is a hepatic necrosis resembling very closely acute yellow atrophy. Phosphorus produces a similar condition, and possibly mercury. Arsenobenzol compounds may cause it. (c) Autogenous poisons, produced in connection with pregnancy and parturition. The ordinary necrotic foci of the liver in pregnancy are the same kind but less in degree than those of acute yellow atrophy.

An exaggeration of any of these forms may lead to a clinical condition which we call acute yellow atrophy. Its association with pregnancy is remarkable. More than half of the cases occur in women, and in a large proportion of these during the middle or latter period of pregnancy. The disease has followed a profound shock or mental emotion. It occurs occasionally in syphilis and other acute infections, and there are cases of cirrhosis of the liver associated with diffuse necrosis, intense jaundice and toxæmia. We are ignorant of the conditions under which toxins cause this widespread necrosis.

Morbid Anatomy.—The liver is greatly reduced in size, looks thin and flattened, and may not have more than one-half or one-third of its normal weight. It is flabby and the capsule is wrinkled. Externally the organ has a greenish-yellow color. On section the color may be yellowish-brown, yellowish-red, or mottled, and the outlines of the lobules are indistinct. The yellow and dark-red portions represent different stages of the same process—the yellow an earlier, the red a more advanced stage. The organ may cut with considerable firmness. The liver-cells are seen in all stages of necrosis, and in spots appear to have undergone complete destruction, leaving a fatty, granular débris with pigment grains and crystals of leucin and tyrosin. Hæmorrhages occur between the liver-cells. There is a cholangitis of the smaller bile-ducts. Marchand, MacCallum, and others have described regenerative changes in the cases which do not run an acute course.

The other organs show extensive bile-staining, and there are numerous hæmorrhages. The kidneys may show marked granular degeneration of the epithelium, and usually there is fatty degeneration of the heart. In a majority of the cases the spleen is enlarged.

Symptoms.—In the initial stage there may be gastro-duodenal catarrh, and the jaundice is thought to be of a simple nature. In some instances this lasts only a few days, in others two or three weeks. Then severe symptoms set in—headache, delirium, trembling of the muscles, and, in some instances, convulsions. The picture may suggest meningitis. Vomiting is a constant symptom, and blood may be brought up. Hæmorrhages occur into the skin or from the mucous surfaces; in pregnant women abortion may occur. The jaundice usually increases, coma sets in and gradually deepens until

death. The body temperature is variable; in a majority of the cases the disease runs an afebrile course, though sometimes just before death there is an elevation. In some instances there has been marked pyrexia. The pulse is usually rapid, the tongue coated and dry, and the patient is in a toxic state. The liver may be enlarged at first but rapidly decreases in size and there may be complete obliteration of the liver dulness. This is due to the flabby organ falling away from the abdominal walls and allowing the intestinal coils to take its place.

The urine is bile-stained and often contains casts. Frequently albuminuria and occasionally albumosuria occur. Urea is markedly diminished. There is a corresponding increase in the percentage of nitrogen present as ammonia which may be increased from the normal 2 to 5 per cent. up to 20 per cent. The diminution in urea is probably partly due to the liver-cells failing to manufacture urea from ammonia, but also in part to organic acids seizing on the ammonia, and thus preventing the formation of urea. Leucin and tyrosin are not constantly present; of 23 cases collected by Hunter, in 9 neither was found; in 10 both were present; in 3 tyrosin only; in 1 leucin only. The leucin and tyrosin are probably derived from the liver cells as a result of their extensive destruction. In the majority of cases no bile enters the intestines, and the stools are clay-colored. The disease is almost invariably fatal. In a few instances recovery has been noted.

The duration and the type of the disease depend upon the extent and the rapidity of progress of the necrosis. Cases have lasted as long as forty days, while death has occurred as early as the second day. A sub-acute form has been described with a slow necrosis lasting many months, associated with jaundice—a protracted stage from which recovery is possible by regeneration of liver tissue, but consecutive cirrhosis is the rule.

Diagnosis.—Jaundice with vomiting, diminution of the liver volume, delirium, and the presence of leucin and tyrosin in the urine, are features characteristic and unmistakable. Leucin and tyrosin are not distinctive. They may be present in other forms of jaundice, some acute infections and leukæmia.

It is not to be forgotten that any severe jaundice may be associated with intense cerebral symptoms. The clinical features in certain cases of cirrhosis are almost identical, but the enlargement of the liver, the more constant occurrence of fever, and the absence of leucin and tyrosin are distinguishing signs. Phosphorus poisoning may closely simulate acute yellow atrophy, particularly in the hæmorrhages, jaundice, and diminution in the liver volume, but the gastric symptoms are usually more marked, and leucin and tyrosin are stated not to occur in the urine.

Treatment.—Efforts should be made to eliminate toxins by free elimination, the giving of alkalis and the use of subcutaneous and intravenous saline injections. Gastric sedatives may be used to allay the vomiting. A milk diet with large amounts of sugar, especially dextrose intravenously, should be given with abundance of alkaline water.

IV. AFFECTIONS OF THE BLOOD-VESSELS OF THE LIVER

Anæmia.—When the liver looks anæmic, as in the fatty or amyloid organ, the blood-vessels, which during life were probably well filled, can be readily injected.

There are no symptoms indicative of this condition.

Hyperæmia.—(a) **ACTIVE HYPERÆMIA.**—After each meal the rapid absorption by the portal vessels induces transient congestion of the organ, which is entirely physiological: but it is quite possible that in persons who persistently eat and drink too much this active hyperæmia may lead to functional disturbance and in the case of too much alcohol, to organic change. In the fevers an acute hyperæmia may be present.

The *symptoms* are indefinite. Possibly the sense of distress or fullness in the right hypochondrium, so often mentioned by dyspeptics and by those who eat and drink freely, may be due to this cause. There are probably diurnal variations in the volume of the liver. In cirrhosis with enlargement the rapid reduction in volume after a copious hæmorrhage indicates the important part which hyperæmia plays even in organic troubles. Andrew H. Smith described a case of periodical enlargement of the liver.

(b) **PASSIVE CONGESTION.**—This is much more common and results from an increase of pressure in the efferent vessels or sub-lobular branches of the hepatic veins. Every condition leading to venous stasis in the right heart at once affects these veins. In chronic valvular disease, myocardial insufficiency, fibrosis of the lung, and intrathoracic tumors mechanical congestion occurs and finally leads to definite changes. The liver is enlarged, firm, and of a deep-red color; the hepatic vessels are greatly engorged, particularly the central vein in each lobule and its adjacent capillaries. On section the organ presents a peculiar mottled appearance, owing to the deeply congested hepatic and the anæmic portal territories; hence the term *nutmeg* given to this condition. Gradually the distention of the central capillaries reaches such a grade that atrophy of the intervening liver-cells is induced. Brown pigment is deposited about the centre of the lobules and the connective tissue is greatly increased. In this cardiac liver the organ is large in the early stage, but later it may become contracted. Occasionally in this form the connective tissue is increased about the lobules as well, but the process usually extends from the sub-lobular and central veins.

The *symptoms* are not always to be separated from those of the associated conditions. Gastro-intestinal catarrh is usually present and hæmatemesis may occur. The portal obstruction in advanced cases leads to ascites, which may precede the development of general dropsy. There is often slight jaundice, the stools may be clay-colored, and the urine contains bile-pigment. The liver is increased in size, may be a full hand's breadth below the costal margin and tender on pressure. There is pain if the enlargement has been rapid. It is in this condition particularly that we find pulsation of the liver. We must distinguish communicated pulsation from the heaving, diffuse impulse due to regurgitation into the hepatic veins, in which the whole liver dilates with each impulse.

The *diagnosis* is usually clear except in cases in which the myocardial

weakness is not very evident. The results of cardiac treatment are of aid in the diagnosis from cirrhosis or syphilis. The indications for *treatment* are to restore the balance of the circulation and to unload the engorged portal vessels. In cases of intense hyperæmia 20 ounces of blood may be directly aspirated from the liver. The diet should be mostly milk and it may be well to keep down the amount of water for a few days. The bowels should be freely opened and watery stools secured. An enema should be given followed by calomel, a compound cathartic pill or elaterin (gr. 1/10, 0.006 gm.) and full doses of Epsom salts repeated as necessary. Dry cups over the liver may be used. The causal condition should be treated.

Diseases of the Portal Vein.—(a) THROMBOSIS; ADHESIVE PYLEPHLEBITIS.—Coagulation of blood in the portal vein is met with in cirrhosis, in syphilis of the liver, invasion of the vein by cancer, proliferative peritonitis involving the gastro-hepatic omentum, perforation of the vein by gall-stones, and occasionally follows sclerosis of the walls of the portal vein or of its branches. In rare instances a complete collateral circulation is established, the thrombus undergoes the usual change, and ultimately the vein is represented by a fibrous cord, a condition which has been called *pylephlebitis adhesiva*. In a case of this kind the portal vein was represented by a narrow fibrous cord; the collateral circulation, which must have been established for years, ultimately failed, ascites and hæmatemesis supervened and rapidly proved fatal. The diagnosis can rarely be made. A suggestive combination is a sudden onset of the most intense engorgement of the branches of the portal system, leading to hæmatemesis, melæna, ascites, and swelling of the spleen.

Infarcts (anæmic or hæmorrhagic) are not common in the liver. They occur in obstruction of the portal vessels, or of the portal and hepatic veins at the same time, occasionally in disease of the hepatic artery.

(b) SUPPURATIVE PYLEPHLEBITIS is considered in the section on abscess.

Affections of the hepatic vein are extremely rare. Dilatation occurs in cases of chronic enlargement of the right heart, from whatever cause. Emboli occasionally pass from the right auricle into the hepatic veins. Of obstruction of the hepatic veins less than 50 cases have been reported. There are acute enlargement of the liver with a rounded edge, pain on pressure and ascites (transudate) which contains red cells and does not clot readily. The duration may be days to years.

Hepatic Artery.—Enlargement of this vessel is seen in cases of cirrhosis of the liver. It may be the seat of extensive sclerosis. Aneurism of the hepatic artery is rare and will be referred to in the section on arteries.

V. DISEASES OF THE BILE-PASSAGES AND GALL-BLADDER

I. CATARRHAL JAUNDICE

Definition.—Jaundice due to hepatitis and cholangitis, and sometimes associated with obstruction of the terminal portion of the common duct.

Etiology.—General catarrhal inflammation of the bile-ducts is usually associated with gall-stones. Catarrhal jaundice may be due to an extension

Rec'd
7. 66
Supp

of a gastro-duodenal infection. The mucous membrane is swollen, and a plug of inspissated mucus fills the diverticulum of Vater, and the narrower portion just at the orifice, completely obstructing the outflow of bile. In one case at post mortem the orifice was found plugged with inspissated mucus, the common and hepatic ducts were slightly distended and contained a bile-tinged mucus, and there were no observable changes in the mucosa of the ducts. In other cases an infection of the finer ducts within the liver occurs which may be due to infection from the intestine. There is evidence of disturbance of the liver function; some degree of hepatitis is probably always present. The van den Bergh test gives varying results so that probably there is a combination of obstructive and toxic and infective jaundice.

This catarrhal or simple jaundice results from the following causes: (a) Duodenal catarrh, in whatever way produced, most commonly following an attack of indigestion. It is most frequent in young persons, but may occur at any age, and may follow not only errors in diet, but also cold and exposure, as well as the conditions associated with portal obstruction, chronic heart-disease, and nephritis. (b) Emotional disturbances may be followed by jaundice in rare cases; the anatomical condition is unknown. (c) Simple or catarrhal jaundice may occur in epidemic form. (d) Catarrhal jaundice is occasionally seen in the infectious fevers. The nature of acute catarrhal jaundice is still unknown, but it is probably an infection with resulting hepatitis and cholangitis. In favor of this view are the occurrence in epidemic form and the presence of slight fever.

Symptoms.—There may be neither pain nor distress, and the patient's friends may first notice the yellow tint, or the patient may observe it in the looking-glass. In other instances there are dyspeptic symptoms and uneasy sensations in the hepatic region or pains in the back and limbs. In the epidemic form the onset may be more severe, with headache, chill, and vomiting. Fever is rarely present, though the temperature may reach 101°, sometimes 102°. All the signs of obstructive jaundice are present, the stools are clay-colored, and the urine contains bile-pigment. The skin has a bright-yellow tint; the greenish, bronzed color is never seen in the simple form. Spider angiomata may occur on the face in catarrhal jaundice. They disappear in a few months. The pulse may be normal, but occasionally it is remarkably slow, and may fall to 40 or 30 beats in the minute, and the respirations to as low as 8 per minute. Sleepiness may be present and rarely a comatose state. The liver may be normal in size, but is usually slightly enlarged, and the edge can be felt below the costal margin. Occasionally the enlargement is more marked. As a rule the gall-bladder can not be felt. The spleen may be increased in size. The duration is from four to eight weeks. There are mild cases in which the jaundice disappears within two weeks; on the other hand, it may persist for three months or even longer. The stools should be carefully watched, for they give the first intimation of removal of the obstruction.

Diagnosis.—This is rarely difficult. The onset in young, comparatively healthy persons, the moderate icterus, the absence of pain and emaciation or evidences of cirrhosis or cancer usually make the diagnosis easy. Cases which persist for two or three months cause uneasiness, as the suspicion is aroused that it may be more than simple catarrh. There are instances in which time

alone can determine the true nature of the case. The possibility of other forms must be borne in mind in anomalous types.

Treatment.—The diet should be simple and the fats restricted. Measures should be used to allay gastric catarrh, if it is present. A dose of calomel may be given, and the bowels kept open subsequently by salines. The patient should not be violently purged. Daily lavage of the stomach with water at 95° is useful. Bismuth and bicarbonate of soda may be given, and the patient should drink freely of alkaline mineral waters. The method of drainage of the bile-ducts devised by Lyon, in which a 25 per cent. solution of magnesium sulphate is introduced into the duodenum, relaxing the sphincter of the common duct, by which large amounts of bile can be drained from the bile passages is of great value. By the use of this method the duration is usually greatly shortened, especially if it is done early.

II. CHRONIC ANGIOCHOLITIS

This may possibly occur as a sequel of an acute process but it is unusual to see a chronic, persistent jaundice due to this cause. A chronic catarrh always accompanies obstruction in the common duct, whether by gall-stones, neoplasm, stricture, or external pressure. There are two groups of cases:

With Complete Obstruction of the Common Duct.—In this form the bile-passages are greatly dilated, the common duct may reach the size of the thumb or larger, there is usually dilatation of the gall-bladder and of the ducts within the liver. The contents of the ducts and of the gall-bladder are a clear, colorless mucus. The mucosa may be everywhere smooth and not swollen. The clear mucus is usually sterile. The patients are the subjects of chronic jaundice, usually without fever.

With Incomplete Obstruction of the Duct.—There is pressure on the duct or there are gall-stones, single or multiple, in the common duct or in the diverticulum of Vater. The bile-passages are not so much dilated, and the contents are a bile-stained, turbid mucus. The gall-bladder is rarely much dilated. In a majority of all cases stones are found in it.

The symptoms of this form of angiocholitis are sometimes very distinctive. With it is associated most frequently the so-called hepatic intermittent fever, recurring attacks of chills, fever, and sweats. It is important to bear in mind that the chills, fever, and sweats do not necessarily mean suppuration.

III. SUPPURATIVE AND ULCERATIVE ANGIOCHOLITIS

The condition is a diffuse, purulent angiocholitis involving the larger and smaller ducts. In a large proportion of all cases there is associated suppurative disease of the gall-bladder. In all forms of infection of the bile passages cultures of the duodenal contents may give information as to the infecting organism.

Etiology.—It is the most serious of the sequels of gall-stones. Occasionally a diffuse suppurative angiocholitis follows the acute infectious cholecystitis; this, however, is rare, since fortunately in the latter condition the cystic duct is usually occluded. Cancer of the duct, or foreign bodies, such as lumbricoids or fish bones, are occasional causes. There may be extension from

a suppurative pylephlebitis. In rare instances suppurative cholangitis occurs in the acute infections, as pneumonia and influenza.

The common duct is greatly dilated and may reach the size of the index finger or the thumb; the walls are thickened, and there may be fistulous communications with the stomach, colon, or duodenum. The hepatic ducts and their extensions in the liver are dilated and contain pus mixed with bile. On section of the liver small abscesses are seen, which correspond to the dilated suppurating ducts. The gall-bladder is usually distended, full of pus, and with adhesions to the neighboring parts, or it may have perforated.

Symptoms.—The symptoms of suppurative cholangitis are usually very severe. A previous history of gall-stones, the development of a septic fever, the swelling and tenderness of the liver, the enlargement of the gall-bladder, and the leucocytosis are suggestive features. Jaundice is always present, but is variable. In some cases it is very intense, in others it is slight. There may be very little pain. There are progressive emaciation and loss of strength. In one case parotitis developed which subsided without suppuration.

Treatment.—With infection of the bile passage, the diet should be simple and water taken freely. Hexamine may be given in full dosage. Lyon's method of non-surgical biliary drainage should always be tried. In some cases surgical drainage of the gall-bladder has been of use. Vaccines prepared from duodenal cultures may be tried.

IV. ACUTE CHOLECYSTITIS

Etiology.—Acute inflammation of the gall-bladder is due to bacterial invasion, with or without the presence of gall-stones. Three varieties or grades may be recognized: the catarrhal, the suppurative, and the phlegmonous. The condition is very serious, may be fatal, and may require prompt surgical intervention for its relief.

Acute non-calculous cholecystitis is a result of bacterial invasion, probably often from foci in the mouth and throat. The colon bacillus, the typhoid bacillus, staphylococci and streptococci are the organisms most often found. The frequency of gall-bladder infection in the fevers, particularly in typhoid fever, has been mentioned. In many cases the organisms are found in the wall of the gall-bladder when the contents are sterile.

The infection may be carried by the lymphatics, by the bile, by the blood, or by the bile ducts. With infection there are changes (1) in the mucous membrane, (2) in the wall, (3) in the peritoneal surface, tending to cause adhesions, and (4) in the bile in the gall-bladder. The relative proportion of these varies greatly but they tend to be progressive.

Pathology.—The organ is usually distended and the walls tense. Adhesions may have formed with the colon or the omentum. In the acute stage the mucous membrane is swollen and the amount of mucin increased. As the process continues the mucosa becomes thickened, the epithelium desquamates, there are areas of necrosis, and the villi may be hypertrophied and stand out, giving a strawberry appearance. With obstruction of the duct and pyogenic infection there may be acute necrotic cholecystitis, with rapid perforation, or a more chronic purulent cholecystitis—empyema of the gall-bladder.

Symptoms.—Severe paroxysmal pain is, as a rule, the first indication, most commonly in the right side of the abdomen in the region of the liver. It may be in the epigastrium or low down in the region of the appendix. "Nausea, vomiting, rise of pulse and temperature, prostration, distention of the abdomen, rigidity, general tenderness becoming localized" usually follow (Richardson). In this form, without gall-stones, jaundice is not often present. Signs at the base of the right lung are common in any form of acute biliary infection. Leucocytosis is common. The local tenderness is extreme, but it may be deceptive in its situation. Due probably to the adhesion and inflammatory processes between the gall-bladder and the bowel are the intestinal symptoms; there may be complete stoppage of gas and faeces; indeed, the operation for acute obstruction has been performed in several cases. The distended gall-bladder may sometimes be felt. As a sequel there may be purulent distention or empyema. In the early stages of some cases, probably with catarrhal changes, the symptoms may be mainly gastric.

Diagnosis.—This is by no means easy, as the symptoms may not indicate the section of the abdomen involved. Appendicitis or acute intestinal obstruction may be diagnosed. The history is often a valuable guide. Occurring during convalescence from typhoid fever or in a patient with previous cholecystitis, such a group of symptoms is highly suggestive. The differentiation of the variety of the cholecystitis is difficult. In the diagnosis of all infections of the bile tract the study by Lyon's method of the bile and its contents may be of great aid. For details his book on the subject should be consulted. In the acute suppurative and phlegmonous forms the symptoms are usually more severe, perforation is very apt to occur, with local or general peritonitis, and unless operative measures are undertaken death ensues.

There is an acute cholecystitis, probably an infective form, in which the patient has recurring attacks of pain in the region of the gall-bladder. The diagnosis of gall-stones is made, but an operation shows simply an enlarged gall-bladder filled with mucus and bile, and the mucous membrane perhaps swollen and inflamed.

Treatment.—The patient should be at rest, given a simple fluid diet, and take water freely. The bowels are kept open by enemata and simple salines. An ice bag is applied over the gall-bladder region. Sodium salicylate or hexamine may be given by mouth (of each gr. 15, 1 gm. t. i. d.). Lyon's method of bile duct drainage often gives excellent results. In the milder forms the inflammation subsides gradually; in severer form operation is indicated and the results are excellent. Increase in the local signs, an enlarged gall-bladder, increasing leucocytosis and fever, are usually indications for operation. Foci of infection should be properly treated.

V. CHRONIC CHOLECYSTITIS

This occurs in a number of different forms, as, for example, an atrophic sclerotic and an ulcerative form.

Etiology.—It often results from a previous attack of acute cholecystitis or may be associated with gall-stones or chronic infection of the ducts. In some cases it is undoubtedly chronic from the onset, resulting from a persistent infection which is never acute enough to set up an active attack. The

infection may be hematogenous, from foci of infection, by the portal system or from the liver.

Pathology.—The gall-bladder is usually distended and contains thick bile and mucus. The walls may be thickened. There may be destruction of the villi and a deposit of lipoid material in the mucous membrane—"strawberry gall-bladder." Later small ulcers may result, fibrous changes occur and stones may form. The mucosa may be atrophic and sometimes the gall-bladder is small and sclerotic; it may be surrounded by a mass of dense adhesions. The relationship between the lymphatics of the gall bladder and pancreas is important in explaining the association of infection in these organs.

Symptoms.—These are much the same as those from gall-stones and a differential diagnosis may be impossible. Flatulency after meals, complaint of fullness after a small meal, a sudden sensation of nausea sometimes with a feeling of faintness, a feeling of cold or slight chilly sensations, and sometimes regurgitation into the mouth are among the symptoms. The stomach contents are variable; perhaps hyperacidity is the most common. The persistence of the symptoms and the lack of results from ordinary treatment are important. The X-ray study may show an enlarged gall-bladder. Jaundice occurs in some cases, varying from time to time. The co-existence of ulcer, gastric or duodenal, and cholecystitis is not rare. There may be attacks of acute pain. In the intervals there may be an entire absence of any tenderness in the gall-bladder region. Sometimes the gall-bladder is palpable. W. J. Mayo called attention to a form of chronic cholecystitis without gall-stones and accompanied with chronic interlobular pancreatitis in which the mucous membrane shows a strawberry-like appearance. The process is confined to the gall-bladder; the glands along the ligament may be enlarged. The chief symptom is pain in the region of the gall-bladder, but there is no distention and the chronic pancreatitis is not always expressed clinically.

Treatment.—The medical management is much the same as in gall-stones; a simple diet, large amounts of water, keeping the bowels freely open and taking regular exercise. The administration of salicylate of sodium and hexamine seems sometimes to be of use. The taking of salines before breakfast is often helpful. In many cases non-surgical drainage (Lyon) is advisable. It may relieve the symptoms materially and done at intervals keep the disturbance to a minimum. In many patients it is an excellent preparation for operation. The decision as to surgical interference must depend on the severity of the symptoms and the interference with health due to the condition. In some cases adhesions are present between the gall-bladder and the colon, pylorus and duodenum, which may be recognized by the X-ray examination. Operation may be justified to correct them. If there is distinct evidence of a chronic suppurative process in the gall-bladder, surgical measures are indicated and should not be delayed.

VI. CANCER OF THE BILE-PASSAGES

Incidence.—Of 3,908 operations on the gall-bladder and biliary passages, in 85 or 2.1 per cent. cancer was found (Mayo). Cancer of the gall-bladder is more common in women, 3 to 1 (Musser), and in three-fourths of the cases

gall-stones are or have been present. The fundus of the bladder is usually attacked first. Primary carcinoma of the bile-ducts is rare.

Symptoms.—When the disease involves the gall-bladder there is usually a history suggesting previous gall-bladder disease. The first symptom is discomfort or pain in the gall-bladder region, made worse by meals and by any jolting. Gastric disturbance is marked. A tumor is felt in a majority of cases, variable in size, occasionally very large, due to distention of the gall-bladder or to involvement of contiguous parts. It is usually very firm and hard. Jaundice is usually due to involvement of the liver; it was present in 69 per cent. of Musser's cases; pain is often of great severity and paroxysmal in character. The pain and tenderness on pressure persist in the intervals between the paroxysmal attacks. There is loss of weight, sometimes fever and sweats. When the liver becomes involved the picture is that of carcinoma of the organ.

Primary malignant disease in the *bile-ducts* is less common, and rarely forms tumors that can be felt externally. The tumor is usually in the common duct, 72 of 90 cases collected by Rolleston. There is usually an early, intense, and persistent jaundice. Pain is variable. The gall-bladder is usually enlarged in obstruction of the common duct by malignant disease. The dilated gall-bladder may rupture. At best the *diagnosis* is doubtful, unless cleared up by an exploratory operation. A very interesting form of malignant disease of the ducts is that which involves the diverticulum of Vater of which Rolleston collected 23 cases. Medical *treatment* is symptomatic.

Removal has little chance of success unless operation is done early but except when there is evidence of metastases it is well to advise the attempt.

VII. STENOSIS AND OBSTRUCTION OF THE BILE-DUCTS

Stenosis.—Stenosis or complete occlusion very rarely follows ulceration, most commonly after the passage of a gall-stone. In these instances the obstruction is usually low down in the common duct. Foreign bodies, such as the seeds of fruits, may enter the duct, and round worms may crawl into it. Liver-flukes and echinococci are rare causes of obstruction in man.

Obstruction.—Obstruction by pressure from without may be due to cancer of the head of the pancreas, less often a chronic interstitial inflammation, compressing the terminal portion of the duct, and rarely, cancer of the pylorus. Secondary carcinomatous involvement of the lymph-glands of the liver is a common cause of occlusion of the duct. Rare causes are aneurism of a branch of the coeliac axis of the aorta, and pressure of large abdominal tumors. The most common cause is the presence of gall-stones. Obstruction of the cystic duct may be due to infection.

Symptoms.—The symptoms produced are those of chronic obstructive jaundice. At first, the liver is enlarged but in chronic cases it may be reduced in size, and of a deeply bronzed color. The hepatic intermittent fever is not often associated with complete occlusion of the duct from any cause, but it is most frequent in chronic obstruction by gall-stones. Permanent occlusion of the duct terminates in death. In many cases the con-

ditions which lead to the obstruction are in themselves fatal. The liver, which is not necessarily enlarged, presents a moderate grade of cirrhosis. Cases of cicatricial occlusion may last for years.

DIAGNOSIS.—A history of colic, jaundice of varying intensity, paroxysms of pain, and intermittent fever point to gall-stones. In cancerous obstruction the tumor mass can sometimes be felt in the epigastric region. In cases in which the lymph-glands in the transverse fissure are cancerous the primary disease may be in the pelvic organs or the rectum, or there may be a gastric cancer, which has not given any symptoms. In these cases the examination of other lymphatic glands, as above the clavicle, may be of value. The gall-bladder is usually enlarged in obstruction of the common duct, except in the cases of gall-stones (Courvoisier's law). Great and progressive enlargement of the liver with jaundice and moderate continued fever is more commonly met with in cancer. A careful X-ray study should always be made.

Treatment.—This must depend on the diagnosis. If due to neoplasm little can be done. Drainage of the gall-bladder or its junction to the bowel may give some relief. If caused by gall-stones, operation by an experienced surgeon is indicated.

Congenital Obliteration of the Ducts.—John Thomson, in 1892, collected 49 cases and studied the condition thoroughly. Howard and Wolbach in 1911 brought the cases up to 76 and Holmes in 1919 found 108 cases. Jaundice sets in early, but may be delayed for ten or twelve days, and is progressive and deep. Hæmorrhages in the skin, from the gastro-intestinal tract, and from the umbilical cord have occurred in fully 50 per cent. Nearly half of the patients die within the first month, a few live on for five or six months, but rarely as long as the tenth or twelfth.

Thomson regards congenital malformation as the chief cause, but cholangitis and congenital cirrhosis of the liver are important factors.

VI. CHOLELITHIASIS

No chapter in medicine is more interesting than that which deals with the question of gall-stones. Few affections present so many points for study—chemical, bacteriological, pathological, and clinical. There has been a great advance in our knowledge in two directions: First, as to the mode of formation of the stones, and, secondly, as to the surgical treatment of the cases.

Origin of Gall-stones.—There are three mechanisms specially concerned: (1) infection, (2) stasis, and (3) the cholesterol content of the blood.

(1) *Infection.*—The route may be (a) hæmatogenous, probably the most common, (b) by elimination through the liver, and (c) retrograde. Hæmatogenous infection may be from a focus of infection in any part of the body; disease of the appendix is sometimes responsible. The gall-bladder is a peculiarly favorable habitat for organisms. Streptococci, staphylococci, pneumococci, colon bacilli and typhoid bacilli have been found with varying conditions of the bile. Streptococcus infection is the most frequent. The typhoid bacillus may live indefinitely in the gall-bladder and has been grown in pure culture from the interior of gall-stones. The experimental production of gall-stones has been accomplished by injecting organisms into the gall-

bladders of animals. The calculus associated with infection is composed largely of calcium salts.

(2) *Stasis*.—An inspissated condition of the bile occurs with this and precipitation is likely to occur. A nucleus is thus formed and other elements are deposited on it. The work of Boysen showed that the gall-bladder was not affected when the gall-stones were of the primary bile-pigment calcium type. Inspissation of the bile is favored by pregnancy and the acute infectious diseases. The views of Meltzer on disturbed contrary innervation of the gall-bladder with retention of bile are of interest in this connection.

(3) *Cholesterol*.—In probably 75 per cent. of cases of cholelithiasis there is an increase in the cholesterol content of the blood. In some cases this may be temporary and not present when the existence of gall-stones is recognized. Cholesterol may be of exogenous or endogenous origin. There is often an increase in the blood cholesterol during typhoid fever and in pregnancy. It is evident that with a foreign body present there may be subsequent infection. A study of the cases in which cholesterol stones are found shows that a history of infection is generally lacking. The formation of a cholesterol stone may be favored by an increase in the cholesterol in the blood, by its increased excretion by the liver, or by deposit of material from inspissated bile.

Country.—Gall-stones are less frequent in the United States than in Germany, 6.94 to 12 per cent. (Mosher). They are less common in England than on the Continent.

Age.—The great majority of cases occur between thirty and sixty, forty to fifty being the most common decade. They are rare under twenty-five but cases have occurred in the new-born and in infants.

Sex.—Three-fourths of the cases occur in women. Pregnancy has an important influence. Some post-mortem series show gall-stones present in 25 per cent. of women over 60 years of age.

All conditions which favor stagnation of bile in the gall-bladder predispose to the formation of stones. Among these may be mentioned corset-wearing, visceroptosis, and occupations requiring a "leaning forward" position. Lack of exercise, sedentary occupations, particularly when combined with over-indulgence in food and constipation are also favoring circumstances.

Physical Characters of Gall-stones.—They may be single, in which case the stone is usually ovoid and may attain a very large size. Instances are on record of gall-stones measuring more than 5 inches in length. They may be extremely numerous, ranging from a score to hundreds or even thousands, in which case the stones are very small. When moderately numerous, they show signs of mutual pressure and have a polygonal form, with smooth facets; occasionally, however, five or six gall-stones of medium size are found which are round or ovoid and without facets. They are sometimes mulberry-shaped and very dark, consisting largely of bile-pigments. Again there are small, black calculi, rough and irregular in shape, and varying in size from grains of sand to small shot. These are sometimes known as gall-sand. On section, a calculus contains a nucleus, which consists of cholesterol bile-pigment, rarely a foreign body. The greater portion of the stone is made up of cholesterin, which may form the entire calculus, and is arranged in concentric laminae showing also radiating lines. Salts of lime and magnesia, bile acids, fatty acids, and traces of iron and copper are also found in them. Most gall-stones

consist of from 70 to 80 per cent. of cholesterin, in either the amorphous or crystalline form. The outer layer of the stone is usually harder and brownish in color.

Seat of Formation.—Within the liver itself calculi are occasionally found, but are here usually small and few, and in the form of ovoid, greenish-black grains. A large majority of all calculi are formed in the gall-bladder where the stones in the larger ducts have usually had their origin.

Symptoms.—In some cases gall-stones cause no symptoms directly referable to the gall-bladder which may tolerate the presence of large numbers for an indefinite time. The most common symptoms are digestive; they are variable in time and character but always tend to be persistent. Discomfort, a sense of fullness, flatulency, nausea, and sometimes vomiting are frequent. There may be a sense of weight or oppression in the epigastrium perhaps with a feeling of faintness. Slight chilly sensations may occur at times. There may be attacks of more severe gastric disturbance in which pain is more marked with considerable vomiting. There is often the complaint of pain about the right shoulder or the angle of the right scapula which is described as “going straight through” or radiating from the front. There may be a curious feeling in the right side which the patient has difficulty in describing; it is like a “catch” or “stitch.” Violent exercise or jolting, as in a motor trip, may increase the symptoms. The examination may show tenderness on deep pressure in the region of the gall-bladder or in the epigastrium, with varying resistance and muscle spasm. The pressure may have to be deep and is often done best by the thumb under the costal margin, the patient taking a deep inspiration. The “catch” in the breath may be characteristic.

Jaundice may occur and should be carefully looked for, especially after an increase in the symptoms. The stomach contents show nothing distinctive: hypoacidity is probably most common. There is usually marked constipation. Obstinate attacks of urticaria may occur.

Certain important features are: (1) the mechanical accidents in consequence of migration of the stone or of obstruction, either in the ducts or intestines; (2) the septic, infectious accidents, either local (angiocholitis and cholecystitis with empyema of the gall-bladder, and the fistulæ and abscess of the liver with infection of the neighboring parts) or general, fever and secondary visceral lesions.

BILIARY COLIC.—Gall-stones may become engaged in the cystic or the common duct without producing pain or severe symptoms. More commonly the passage of a stone excites the violent symptoms known as biliary colic. The attack sets in abruptly with agonizing pain in the right hypochondriac region, which radiates to the shoulder, or is very intense in the epigastric and in the lower thoracic regions. It is often associated with a rigor and fever from 102° to 103° . The pain is usually so intense that the patient rolls about in agony with vomiting, profuse sweating, and great depression of the circulation. There may be marked tenderness in the region of the liver, which may be enlarged, and the gall-bladder may become palpable and very tender. In other cases the fever is more marked. The spleen is enlarged (Naunyn) and the urine contains albumin with red blood cells. The symptoms of acute infectious cholecystitis and gall-stone colic are very similar, and

surgeons have operated for the former condition, believing calculi were present. In a large number of the cases jaundice occurs, but it is not a necessary symptom. It does not happen during the passage of the stone through the cystic duct but only when it becomes lodged in the common duct. The pain is due (a) to impaction of the stone about the orifice of the cystic duct or to slow progress in the duct, in which the stone takes a rotary course owing to the arrangement of the Heisterian valve; the cystic duct is poor in muscle fibres but rich in nerves and ganglia; (b) to the acute inflammation which usually accompanies an attack; (c) to the stretching and distention of the gall-bladder.

The attack varies in duration. It may last for a few hours, several days, or even a week or more. If the stone becomes impacted in the orifice of the common duct, the jaundice becomes intense; much more commonly it is a slight transient icterus. The attack of colic may be repeated at intervals for some time, but finally the stone passes and the symptoms disappear.

Occasionally accidents occur, such as rupture of the duct with fatal peritonitis. Fatal syncope and repeated convulsive seizures during an attack are rare events. Palpitation and distress about the heart may be present, and occasionally a mitral murmur occurs during the paroxysm, but the cardiac conditions described as coming on acutely in biliary colic are due to pre-existent myocardial degeneration, not infrequent in patients with gall-stones.

The diagnosis of acute hepatic colic is generally easy. The pain is in the upper abdominal and thoracic regions, whereas in nephritic colic it is in the lower abdomen. A history of previous attacks is an important guide, and the occurrence of jaundice, however slight, determines the diagnosis. To look for gall-stones, the stools should be thoroughly mixed with water and carefully filtered through a narrow-meshed sieve. Concretions due to some fruits, e. g., pears, or to olive oil should not be mistaken for gall-stones. A remarkable xanthoma of the bile-passages has been found in association with hepatic colic. In chronic gall-bladder cases, with adhesions, the clinical picture may resemble closely that of ulcer. The presence of gall-stones may be proved by X-ray examination in a considerable proportion of cases.

OBSTRUCTION OF THE CYSTIC DUCT.—The effects may be thus enumerated: (a) Dilatation of the gall-bladder. In acute obstruction the contents are bile mixed with much mucus or muco-purulent material. In chronic obstruction the bile is replaced by a clear fluid mucus due to absorption of the bile and other contents. By this time the lining is of fibrous tissue and the fluid is a transudate. This is an important point in diagnosis, as such a gall-bladder may form a large tumor. A dilated gall-bladder may reach an enormous size, and in one instance Tait found it occupying the greater part of the abdomen. In such cases it has been mistaken for an ovarian tumor. In one case it was attached to the right broad ligament. The dilated gall-bladder can usually be felt below the edge of the liver, and often has a characteristic outline like a gourd. An enlarged and relaxed organ may not be palpable, and in acute cases the distention may be upward toward the hilus of the liver. The dilated gall-bladder usually projects directly downward, rarely to one side or the other, though occasionally towards the middle line. It may reach below the navel, and in persons with thin walls the outline can be accurately defined. Riedel called attention to a tongue-like *projection* of the

anterior margin of the right lobe in connection with enlarged gall-bladder. Distention of the gall-bladder may occur without jaundice; indeed, the greatest enlargement has been met with in such cases.

PALPATION.—There are two conditions in which gall-stones may be felt; the large, loose, flaccid pouch with numerous stones in a person with a very relaxed abdominal wall—a well-known surgeon described the palpation of gall-stones in himself—and the hard top of the single large ovoid stone about which the walls of the gall-bladder have contracted.

(b) *Cholecystitis*.—The simple form is common, and to it are due probably many of the symptoms of the gall-stone attack. Phlegmonous cholecystitis is rare. Perforation may occur with fatal peritonitis. Chronic cholecystitis in some grade is common and many of the symptoms are due to it. Adhesions may form to the stomach, duodenum or colon. With infection of the common duct, the pancreatic ducts may be involved and chronic pancreatitis result.

(c) *Suppurative cholecystitis* is much less common, and in the great majority of cases is associated with gall-stones. There may be enormous dilatation, and over a litre of pus has been found. Perforation and the formation of abscesses in the neighborhood are not uncommon.

(d) *Calcification* of the gall-bladder may be a termination of the previous condition. There are two forms: incrustation of the mucosa with lime salts and the true infiltration of the wall with lime, the so-called ossification.

(e) *Atrophy* of the gall-bladder is not uncommon. It shrinks into a small fibroid mass, not larger, perhaps, than a good-sized pea or walnut, or even has the form of a narrow fibrous string; more commonly it tightly embraces a stone. This condition is usually preceded by hydrops of the bladder.

(f) Occasionally the gall-bladder presents *diverticula*, which may be cut off from the main portion, and usually contain calculi.

OBSTRUCTION OF THE COMMON DUCT.—There may be a single stone tightly wedged in the duct in any part of its course, or a series of stones, sometimes extending into both hepatic and cystic ducts, or a stone lies in the diverticulum of Vater. There are three groups of cases: (a) In rare instances a stone tightly corks the common duct, causing *permanent occlusion*; or it may partly rest in the cystic duct, and may have caused thickening of the junction of the ducts; or a big stone may compress the hepatic or upper part of the common duct. The jaundice is deep and enduring, and there are no septic features. The pains, the previous attacks of colic, and the absence of enlarged gall-bladder help to separate the condition from obstruction by new growths, although it cannot be differentiated with certainty. The ducts are usually much dilated and everywhere contain a clear mucoid fluid.

(b) *Incomplete Obstruction, with Infective Cholangitis*.—There may be a series of stones in the common duct, a single stone which is freely movable, or a stone (ball-valve stone) in the diverticulum of Vater. These conditions may be found at autopsy, without the subjects having had symptoms pointing to gall-stones; but in a majority there are characteristic features. The common duct may be as large as the thumb; the hepatic duct and its branches through the liver may be greatly dilated, and the distention may be apparent beneath the liver capsule. Great enlargement of the gall-bladder is rarer.

The mucous membrane of the ducts is usually smooth and clear, and the contents consist of a thin, slightly turbid bile-stained mucus.

Naunyn gave as the distinguishing signs of stone in the common duct: "(1) The continuous or occasional presence of bile in the fæces; (2) distinct variations in the intensity of the jaundice; (3) normal size or only slight enlargement of the liver; (4) absence of distention of the gall-bladder; (5) enlargement of the spleen; (6) absence of ascites; (7) presence of febrile disturbance; and (8) duration of the jaundice for more than a year."

In connection with the ball-valve stone, most common in the diverticulum of Vater, though it may be in the common duct itself, there is a special symptom group: (a) Paroxysms with chills, fever, and sweating; the *hepatic intermittent fever* of Chârcot; (b) jaundice of varying intensity, which persists for months or even years, and deepens after each paroxysm; (c) at the time of the paroxysm, pain in the region of the liver with gastric disturbance. These symptoms may continue on and off for three or four years, without the development of suppurative cholangitis. The condition has lasted from eight months to three years. The rigors are of intense severity, and the temperature rises to 103° or 105° F. The chills may recur daily for weeks, so that they are often attributed to malaria. The jaundice is variable, and deepens after each paroxysm. The itching may be most intense. Pain, which is sometimes severe and colicky, does not always occur. There may be marked vomiting and nausea. As a rule there is no progressive deterioration of health. In the intervals between the attacks the temperature is normal.

The history and post-mortem examinations show conclusively that this condition may persist for years without a trace of suppuration within the ducts. It is probable that the toxic symptoms develop only when a certain grade of tension is reached. A valuable diagnostic point is the absence of dilatation of the gall-bladder in cases of obstruction from stone—Courvoisier's rule.

(c) *Incomplete Obstruction with Suppurative Cholangitis*.—When suppurative cholangitis exists the mucosa is thickened, often eroded or ulcerated; there may be extensive suppuration in the ducts throughout the liver, and even empyema of the gall-bladder. Occasionally the suppuration extends beyond the ducts, and there is localized liver abscess or perforation of the gall-bladder with the formation of abscess between the liver and stomach. Clinically it is characterized by fever which may be intermittent, but more commonly is remittent and without prolonged intervals of apyrexia. The jaundice is rarely so intense, nor does it deepen after the paroxysms. There is usually greater enlargement of the liver with tenderness and more definite signs of septicæmia. The course is shorter and recovery never takes place.

THE MORE REMOTE EFFECTS OF GALL-STONES.—(a) *Biliary Fistulæ*.—(1) *Cutaneous*.—The external fistula is the most common, 184 out of 384 cases (Naunyn). A majority occur in the region of the navel, to which part the falciform ligament directs the suppuration. The number of stones discharged varies from one or two to many hundreds. Of the 184 cases in Courvoisier's statistics recovery took place in 78. In rare instances the fistula is in the right iliac fossa, or even in the thigh.

(2) *Gastro-intestinal Fistulæ*.—The duodenal is the most frequent, 108 of 384 cases (Naunyn). Usually the opening is between the fundus of the

gall-bladder and the first part of the duodenum. A big stone may ulcerate through, leaving little or no damage. In other instances the cicatrization leads to obstruction. Communication with the ileum and jejunum is rare.

Fistulæ between the common duct and the duodenum occurred in 15 cases in Naunyn's series. Biliary gastric fistulæ are rare. The vomiting of gall-stones is not necessarily proof of perforation, as in the majority of such cases the stones probably pass up through the pylorus.

(3) Broncho-biliary Fistulæ.—Of J. E. Graham's collected series of 35 cases, 19 were due to gall-stones; 11 to hydatids; 2 to roundworms; and in 2 the cause was doubtful. In many cases the amœbic liver abscess perforating into the lung is followed by a permanent biliary fistula.

(4) Perforation may occur into the *portal vein*, of which a few cases are on record; one, according to tradition, was the famous Ignatius Loyola.

(5) Perforation into the *hepatic artery* or one of its branches is exceedingly rare. Either an erosion from the common duct or an hepatic aneurism may rupture into the gall-bladder.

(6) Fistula into the *urinary passages* may be with the pelvis of the kidney in which the gall-stone has been found, or into the urinary bladder, of which there are few cases on record.

(7) Lastly, the communication between the *pericardium* and the biliary tract is referred to by Naunyn in a single case.

(b) *Perforation into the Peritoneum*.—Of 119 cases (Courvoisier) in 70 the rupture occurred directly into the peritoneal cavity; in 49 an encapsulated abscess formed. As a rule, the condition is due to an acute cholecystitis.

(c) *Intestinal Obstruction by Gall-stones*.—Reference has been made to this; of 295 cases of obstruction, analyzed by Fitz, 23 were by gall-stones. In Courvoisier's statistics of 131 cases, in 6 the calculi had a peculiar situation, as in a diverticulum or in the appendix. Of the remaining 125 cases, in 70 the stone was spontaneously passed, usually with severe symptoms. The post mortem reports show that in some of these cases very large stones have passed, as the gall-duct has been enormously distended, its orifice admitting the finger freely. This, however, is extremely rare. The stones have been found most commonly in the ileum.

Diagnosis.—The frequency of gall-stones in those over 50 years of age, especially women, should be remembered. With hepatic colic or lodgment of a stone in the common duct diagnosis is usually easy but in many cases the symptoms are digestive and do not suggest gall-stones. The persistence and variability of the digestive symptoms with little result from symptomatic treatment are important. The X-ray study by a competent man gives positive results in roughly about half the cases; pure cholesterol stones do not show in X-ray plates. A study by Lyon's method of bile-duct drainage may be of aid. The exclusion of organic stomach disease is usually not difficult. In some cases the diagnosis has to be made of gall-bladder disease, the presence of gall-stones being in doubt.

Prognosis.—The outlook is always uncertain. Many patients carry gall-stones for years without any severe symptoms and with good general health, as post-mortem studies prove. There is always the danger of colic, blocking of a duct, severe infection, or of carcinoma developing. The influence on the patient's comfort and general health may be marked. The presence of

gall-stones is always a danger and after long duration the outlook with operation may be serious owing to complicating conditions.

Treatment.—GENERAL.—The decision for or against surgical treatment must first be made. There are patients in whom the symptoms are so slight that consent to surgery is almost out of the question or the general condition is such that operation involves great risk. As a general rule the condition should be regarded as a surgical one; regret for early operation is rare but common for delay. The patient is safer in the hands of a good surgeon than left to Nature with the assistance that we can give. With persistent symptoms, general ill-health, repeated attacks of colic, or evidence of infection or obstruction of the bile passages, there should be no delay in advising operation. In mild cases the problem should be frankly stated to the patient for decision. Delay to try the effects of careful medical treatment may be accepted but should not be urged. It is most justifiable if the symptoms are recent and mild, without evidence of infection, in elderly patients in whom symptoms have been slight and perhaps have grown less, and in those in whom operation involves great risk.

Foci of infection should be treated and special attention given to the mouth. The patient should take regular exercise. The diet should be simple and in some cases a cholesterol free diet seems useful. (No eggs, liver, kidney or sweetbread and as little fat as possible.) Water should be taken freely. The soda salts are believed to prevent the concentration of the bile; the sulphate or the phosphate may be taken in doses of 1 to 2 drams daily. Some form of salicylate may be useful; acetylsalicylic acid (gr. 5, 0.3 gm.) may be given four or five times a day. Hexamine (gr. 5-10, 0.3-0.6 gm.) four times a day is useful. An alkali, as sodium bicarbonate or magnesia, is sometimes of value and belladonna may relieve discomfort. For the itching McCall Anderson's dusting powder may be used: starch, an ounce (30 gm.); camphor, a dram and a half (6 gm.), and oxide of zinc, half an ounce (15 gm.) Powdering with starch, strong alkaline baths (hot), pilocarpine hypodermically (gr. $\frac{1}{8}$ - $\frac{1}{6}$, 0.008-0.01 gm.), and antipyrin (gr. v, 0.3 gm.), may be tried. Ichthyol and lanolin ointment or menthol ointment (5 per cent.) sometimes gives relief.

In an attack of biliary colic the patient should be kept under morphia, given hypodermically, in quarter-grain (0.016 gm.) doses. In an agonizing paroxysm it is well to give a whiff or two of chloroform until the morphia has had time to act. Great relief is experienced from a hot bath and fomentations in the region of the liver. The patient should be given laxatives and drink copiously of alkaline mineral waters. Olive oil has proved useless in our hands. Since the days of Durande, whose mixture of ether with turpentine is still used in France, various remedies have been advised to dissolve the stones within the gall-bladder, none of which are efficacious.

Surgical treatment, especially if undertaken early, is usually satisfactory. Of 4,000 operations performed by the Mayo brothers to February 20th, 1911, the mortality was 2.57 per cent. Of 2,920 cases in which the gall-bladder alone was involved the mortality was 1.8 per cent. Of 492 cases in which the common duct was involved the mortality was 8 per cent. In 2.25 per cent. there was the complication of malignant disease.

The possibility of the re-formation of stones is very slight. It is prob-

able that in the majority of instances the stones do not re-form, but were incompletely removed. Deaver reports an instance in which 200 stones were removed two years after the extraction of 120. After removal of the gall-bladder stones may be formed in the hepatic ducts.

VII. THE CIRRHOSES OF THE LIVER

General Considerations.—The many forms of cirrhoses of the liver have one feature in common—an increase in the connective tissue. We use the term cirrhosis (by which Laennec characterized the tawny, yellow color of the common atrophic form) to indicate similar changes in other organs.

Etiology.—There are five types of primary lesion, any one of which may lead to cirrhosis.

(1) *Toxic Cirrhosis.*—This is the only acute type and it is seen post partum, in chloroform narcosis and sometimes as a terminal lesion in any form of disease. There is a central necrosis about the hepatic vein which may be slight in amount, or in some cases an acute yellow atrophy, very extensive so that the liver is rapidly reduced in size. Into the necrotic areas leucocytes migrate, the dead liver cells are quickly removed and there is an apparent increase of the connective tissue. Great regeneration of the liver cells is possible. Clinically this type can scarcely be spoken of as cirrhosis.

(2) *Infectious Cirrhosis.*—Adami and his school hold that colon bacilli from the bowel pass to the liver and there gradually excite a slow proliferation of connective tissue, regarding it as a kind of subinfection. Mallory, whose classification is followed, thinks that the only type of true infectious cirrhosis is through the bile ducts, usually when there is bile stasis or gall-stones or other obstructions are present. Cases are described in which invasion occurs along apparently normal bile-ducts, the organisms causing necrosis of the liver cells, proliferation of fibroblasts, and thickening of the walls of the smaller bile ducts which may be dilated and tortuous. Clinically this type is rare, and characterized by chronic jaundice and enlargement of the liver.

(3) *Pigment Cirrhosis.*—This may be an external pigment as in anthracosis in which the irritation of the coal particles reaching the liver through the lymphatics may excite a moderate grade of cirrhosis. The endogenous pigment is a transformation of hæmoglobin as in malaria or hæmochromatosis.

(4) *Syphilitic Cirrhosis.*—Whether congenital or acquired, the essential lesion is produced by the *Treponema pallidum*, either a diffuse proliferation of fibroblasts, or a more localized lesion, the gumma.

(5) *Alcoholic Cirrhosis.*—As a result of the toxic action of the alcohol, the liver cells, singly or in groups, undergo a slow necrosis, following which there is a multiplication of the fibroblasts with a hyalin degeneration of some cells and multiplication of others and an increase in the smaller bile ducts. Fatty infiltration is common, so that the organ may be enlarged.

Of these types the toxic and one form of the alcoholic are associated with contraction, the infectious, the pigmentary and the fatty cirrhosis with enlargement of the organ. Clinically we may consider four forms, the portal, the hypertrophic (of Hanot), the syphilitic, and the capsular.

I. PORTAL CIRRHOSIS

Etiology.—The disease occurs most frequently in middle-aged males who have been addicted to drink. Whisky, gin, and brandy are more potent to cause cirrhosis than beer. It is more common in countries in which strong spirits are used than in those in which malt liquors are taken. It is not always due to alcohol. Symmers believes that syphilis is an important factor in the etiology in the Laennec cirrhosis. Among 1,000 autopsies in the Johns Hopkins Hospital there were 63 cases of small cirrhotic liver, and 8 cases of the fatty cirrhotic organ. Lanceraux claims that the *vin ordinaire* of France is a common cause. Of 210 cases, excess in wine alone was present in 68 cases. He thinks it is the sulphate of potash in the plaster of Paris used to give the “dry” flavor which damages the liver.

Cirrhosis of the liver in young children is not very rare. In a certain number of the cases there is an alcoholic history, in others syphilis has been present, while a third group, due to the poisons of the infectious diseases, embraces a certain number of the cases of Hanot’s hypertrophic cirrhosis.

Morbid Anatomy.—Portal cirrhosis occurs in two well-characterized forms:

THE ATROPHIC CIRRHOSIS OF LAENNEC.—The organ is greatly reduced in size and may be deformed. The weight is sometimes not more than a pound or a pound and a half. It presents numerous granulations on the surface; is firm, hard, and cuts with great resistance. The substance is seen to be made up of greenish-yellow islands surrounded by grayish-white connective tissue. W. G. MacCallum has shown that regenerative changes in the cells are almost constantly present. This yellow appearance of the liver induced Laennec to give to the condition the name of cirrhosis.

THE FATTY CIRRHOTIC LIVER.—Even in the contracted form the fat is increased, but in typical examples of this variety the organ is not reduced in size, but is enlarged, smooth or very slightly granular, anæmic, yellowish-white in color, and resembles an ordinary fatty liver. It is, however, firm, cuts with resistance, and microscopically shows a great increase in the connective tissue. This form occurs most frequently in beer-drinkers.

The essential elements in cirrhosis are destruction of liver-cells with fibrosis and obstruction to the portal circulation.

In a case of cirrhosis with contraction the peritoneum is usually found to contain a large quantity of fluid, the membrane is opaque, and there is chronic catarrh of the stomach and of the small intestines. The spleen is enlarged, in part, at least, from the chronic congestion, possibly due in part to a toxic influence. The pancreas frequently shows interstitial changes. The kidneys are sometimes sclerotic, the bases of the lungs may be compressed by the ascitic fluid, the heart often shows marked degeneration, and arterio-sclerosis is usually present. A remarkable feature is the association of acute tuberculosis with cirrhosis. In seven cases of our series the patients died with acute tuberculous peritonitis or acute tuberculous pleurisy. Rolleston found that tuberculosis was present in 29 per cent. of 706 fatal cases of cirrhosis. Peritoneal tuberculosis was found in 9 per cent. of a series of 584 cases.

The compensatory circulation is carried out by the following vessels: (1) The accessory portal system of Sappey, of which important branches pass in the round and suspensory ligaments and unite with the epigastric and mammary systems. These vessels are numerous and small. Occasionally a large single vein, which may attain the size of the little finger, passes from the hilus of the liver, follows the round ligament, and joins the epigastric veins at the navel. Although this has the position of the umbilical vein, it is usually a para-umbilical vein—that is, an enlarged vein by the side of the obliterated umbilical vessel. Rarely there is about the navel a bunch of varices, the so-called *caput Medusæ*. Other branches of this system occur in the gastro-epiploic omentum, about the gall-bladder, and, most important of all, in the suspensory ligament. These latter form large branches, which anastomose freely with the diaphragmatic veins, and so unite with the vena azygos. (2) By the anastomosis between the œsophageal and gastric veins. The veins at the lower end of the œsophagus may be enormously enlarged, producing varices which project on the mucous membrane. (3) The communications between the hæmorrhoidal and the inferior mesenteric veins. The freedom of communication here is variable, and the hæmorrhoidal veins may not be much enlarged. (4) The veins of Retzius, which unite the radicles of the portal branches in the intestines and mesentery with the inferior vena cava and its branches. To this system belongs the whole group of retroperitoneal veins, which are in most instances enormously enlarged, particularly about the kidneys, and which carry a considerable proportion of the portal blood.

Symptoms.—The most extreme grade of portal cirrhosis may exist without symptoms. So long as the compensatory circulation is maintained the patient may suffer little or no inconvenience. The remarkable efficiency of this collateral circulation is well seen in those rare instances of permanent obliteration of the portal vein. The symptoms may be divided into two groups—obstructive and toxic.

OBSTRUCTIVE.—The overfilling of the blood-vessels of the stomach and intestine leads to chronic catarrh, and the patients suffer with nausea and vomiting, particularly in the morning; the tongue is furred and the bowels are irregular. Hæmorrhage from the stomach may be an early symptom; it is often profuse and liable to recur but seldom proves fatal. The amount vomited may be remarkable; one patient vomited ten pounds in seven days. Following the hæmatemesis melæna is common; but hæmorrhages from the bowels may occur for several years without hæmatemesis. The bleeding very often comes from œsophageal varices. Epistaxis sometimes occurs. Enlargement of the *spleen* may be due to toxæmia. The organ can usually be felt. Evidences of the establishment of the collateral circulation are seen in the enlarged epigastric and mammary veins, more rarely in the presence of the caput Medusæ and the development of hæmorrhoids. The distended venules in the lower thoracic zone along the line of attachment of the diaphragm are not specially marked in cirrhosis. The most striking feature of failure in the compensatory circulation is *ascites*, the effusion of serous fluid into the peritoneal cavity, which may appear suddenly. The conditions under which this occurs are obscure. In some cases it is due more to chronic peritonitis and perihepatitis than to the cirrhosis. The abdomen gradually distends,

may reach a large size, and contain as much as 15 to 20 litres. Œdema of the feet may precede or develop with the ascites. The dropsy is rarely general.

Jaundice is usually slight, and was present in 107 of 293 cases of cirrhosis collected by Rolleston. The skin has frequently a sallow, slightly icteroid tint. The gastric secretions are usually reduced. The urine is often reduced in amount, contains urates in abundance, often a slight amount of albumin, and, if jaundice is intense, casts. The disease may be afebrile throughout, but in many cases, as shown by Carrington, there is slight fever, from 100° to 102.5° F.

Examination at an early stage may show an enlarged and painful liver. In many of the cases of portal cirrhosis the organ is "enlarged at all stages of the disease, and, whether enlarged or contracted, the clinical symptoms and course are much the same" (Foxwell). A decrease in the size of the liver under observation may be a striking feature. The patient may first come under observation for dyspepsia, hæmatemesis, slight jaundice, or nervous symptoms. Later in the course the patient has an unmistakable hepatic facies; he is thin, the eyes are sunken, the conjunctivæ watery, the nose and cheeks show distended venules, and the complexion is muddy or icteroid. On the enlarged abdomen the vessels are distended, and a bunch of dilated veins may surround the navel. A *venous hum*, sometimes accompanied by a thrill, may be heard in the epigastrium or over varicosities. Nævi of a remarkable character may appear on the skin, either localized stellate varices—spider angiomas—usually on the face, neck, and back, and also "mat" nævi—areas of skin of a reddish or purplish color due to the uniform distention of small venules. When much fluid is in the peritoneum it is impossible to make a satisfactory examination, but after withdrawal the area of liver dulness can be determined and on deep pressure the edge of the liver can be detected, and occasionally the hard, firm, and even granular surface. The spleen is often palpable. Examination of the anus may reveal the presence of hæmorrhoids.

TOXIC SYMPTOMS.—At any stage the patient may have cerebral symptoms, a noisy delirium, or stupor, coma, or even convulsions. The condition is not infrequently mistaken for uræmia. The nature of the toxic agent is not settled. Without jaundice, and not attributable to cholæmia, the symptoms may come on in hospital when the patient has not had alcohol for weeks.

The fatty cirrhotic liver may produce symptoms similar to those of the contracted form, but more frequently it is latent and is found accidentally in toppers who have died from various diseases. A number of the cases clinically diagnosed as cirrhosis with enlargement come in this division.

Diagnosis.—In the early stages one can only be suspicious. With ascites, a well-marked history of alcoholism, the hepatic facies, and hæmorrhage from the stomach or bowels, the diagnosis is rarely doubtful. If, after withdrawal of the fluid, the spleen is found to be enlarged and the liver either not palpable or, if it is enlarged, hard and regular, the probabilities in favor of cirrhosis are very great. In the early stages, when the liver is increased in size, it may be impossible to say whether it is a cirrhotic or a fatty liver. The differential diagnosis between common and syphilitic cirrhosis can usually be made. A marked history of syphilis or the existence of other

syphilitic lesions, with irregularity on the surface or at the edge of the liver, and relatively greater enlargement of the left lobe, are in favor of the latter. Thrombosis or obliteration of the portal vein can rarely be differentiated. In a case of fibroid transformation of the portal vein, the collateral circulation had been established for years, and the symptoms were simply those of extreme portal obstruction, such as occur in cirrhosis. Thrombosis of the portal vein may occur in cirrhosis and be characterized by a rapidly developing ascites. The cardiac liver is usually easily recognized. Splenic anæmia with cirrhosis may give difficulty, but the degree of splenomegaly, marked secondary anæmia and leucopenia are usually distinctive.

Prognosis.—The outlook is bad. When the collateral circulation is fully established the patient may have no symptoms whatever. There are instances of enlargement of the liver, slight jaundice, cerebral symptoms, and even hæmatemesis, in which the liver becomes reduced in size, the symptoms disappear, and the patient may live in comparative comfort for years. There are cases, too, possibly syphilitic, in which, after one or twoappings, the symptoms disappeared and the patients apparently recovered. The occurrence of fever and toxic symptoms, nephritis and acute tuberculous disease are ominous. Ascites is a serious event, especially if due to the cirrhosis alone and not to an associated peritonitis. Of 34 cases with ascites 10 died before tapping was necessary; 14 were tapped, and the average duration of life after the swelling was first noticed was only eight weeks; of 10 cases the diagnosis was wrong in 4, and in the remaining 6, who were tapped oftener than once, chronic peritonitis and perihepatitis were present (Hale White).

II. HYPERTROPHIC BILIARY CIRRHOSIS (*Hanot*)

This form was first described by Requin in 1846, but our accurate knowledge of it dates from the work of Hanot (1875), whose name it bears in France—*maladie de Hanot*. It is a rare disease.

Cirrhosis with enlargement occurs in portal cirrhosis; there is an enlarged fatty and cirrhotic liver of alcoholics, a pigmentary form occurs in hæmochromatosis, and in syphilis the organ is often very large. The hypertrophic cirrhosis of Hanot is easily distinguished from these forms.

Etiology.—Males are more often affected than females—in 22 of Schachmann's 26 cases. The subjects are young; some of the cases in children probably belong to this form. Alcohol plays a minor part, and not one of our patients had been a heavy drinker. The etiology is obscure; chronic infection may be responsible.

Morbid Anatomy.—The organ is enlarged, weighing from 2,000 to 4,000 grams. The form is maintained, the surface is smooth, or presents small granulations; the color in advanced cases is of a dark olive green; the consistence is greatly increased. The section is uniform, greenish yellow in color, and the liver nodules may be seen separated by connective tissue. The bile-passages present nothing abnormal. The cirrhosis is mono- or multilobular, with a connective tissue rich in round cells. The bile-vessels are the seat of an angiocholitis, catarrhal and productive, and there is an extraordinary development of new biliary canaliculi. The liver-cells are neither fatty nor pigmented, and may be increased in size and show karyokinetic figures.

From the supposed origin about the bile-vessels it has been called biliary cirrhosis. The spleen is greatly enlarged and may weigh 600 or more grams.

Symptoms.—The cases occur in young persons; there is not, as a rule, an alcoholic history, and males are usually affected. The features are: (a) A remarkably chronic course of from four to six, or even ten years. (b) Jaundice, usually slight, often not more than a lemon tint, or a tinging of the conjunctivæ. At any time during the course an icterus gravis, with high fever and delirium, may develop. There is bile in the urine; the stools are not clay colored as in obstructive jaundice, but may be very dark. (c) Attacks of pain in the region of the liver, which may be severe and associated with nausea and vomiting. The pain may be slight and dragging, and in some cases is not at all a prominent symptom. The jaundice may deepen after attacks of pain. (d) Enlarged liver. A fullness in the upper abdominal zone may be the first complaint and the enlargement may be very marked. In one of our cases the left lobe was unusually prominent and stood out almost like a tumor. Exploration showed only an enlarged, smooth organ without adhesions. On palpation the hypertrophy is uniform, the consistence is increased, and the edge distinct and hard. The gall-bladder is not enlarged. The vertical flatness is much increased and may extend from the sixth rib to the level of the navel. (e) The spleen is enlarged, easily palpable, and very hard. (f) Certain negative features are of moment—the usual absence of ascites and of dilatation of the subcutaneous veins of the abdomen. Among other symptoms may be mentioned hæmorrhages. One patient had bleeding at the gums for a year; another had had for years most remarkable attacks of purpura with urticaria. Pruritus, xanthoma, lichen, and telangiectasis may be present in the skin. The skin may become very bronzed, almost as deeply as in Addison's disease. Slight fever may be present, which increases during the crises of pain. There may be a marked leucocytosis. A curious attitude of the body has been seen, in which the right shoulder and right side appear dragged down. The patients die with the symptoms of icterus gravis, from hæmorrhage, from an intercurrent infection, or in a profound cachexia. Certain of the cases of cirrhosis of the liver in children are of this type; the enlargement of the spleen may be very pronounced.

Diagnosis.—The chronicity, the age, the jaundice with enlarged liver and spleen, and the absence of ascites aid in the distinction from portal cirrhosis with enlargement. Splenic anæmia should not give difficulty, the blood findings, the absence of jaundice (except with a small liver), and the absence of marked hepatic enlargement should be distinctive. The marked smooth enlargement of syphilis may cause error if its possibility is not considered.

III. SYPHILITIC CIRRHOSIS

This is considered in the section on syphilis (p. 281). It is referred to again to emphasize (1) its frequency; (2) the great importance of its differentiation from the alcoholic form; (3) its curability in many cases; and (4) the tumor formations in connection with it.

IV. CAPSULAR CIRRHOSIS—PERIHEPATITIS

Local capsulitis is common in many conditions of the liver. The form of disease here described is characterized by an enormous thickening of the entire capsule, with great contraction of the liver, but not necessarily with special increase in the connective tissue of the organ itself. Our chief knowledge of the disease we owe to the Guy's Hospital physicians, particularly to Hilton Fagge and to Hale White, who collected 22 cases from the records. The liver substance itself was "never markedly cirrhotic; its tissue was nearly always soft." Chronic capsulitis of the spleen and a chronic proliferative peritonitis are almost invariably present. In 19 of the 22 cases the kidneys were granular. Hale White regards it as a sequel of interstitial nephritis. The youngest case in his series was twenty-nine. The symptoms are those of portal cirrhosis—ascites, often recurring and requiring many tapplings. Jaundice is not often present. There are two groups of cases—the one in adults usually with ascites is regarded as ordinary cirrhosis and the diagnosis is rarely made. Signs of interstitial nephritis, recurring ascites, and absence of jaundice are regarded by Hale White as important diagnostic points. In the second group the perihepatitis, perisplenitis, and proliferative peritonitis are associated with adherent pericardium and chronic mediastinitis. In one such case the diagnosis of capsular hepatitis was very clear, as the liver could be grasped in the hand and formed a rounded, smooth organ resembling the spleen. The child was tapped 121 times (*Archives of Pædiatrics*, 1896).

Treatment of the Cirrheses.—The portal function of the liver may be put out of action without much damage to the body. There may be an extreme grade of cirrhotic atrophy without symptoms; the portal vein may be obliterated, or, experimentally, the portal vein may be anastomosed with the cava. So long as there is an active compensatory circulation a patient with portal cirrhosis may remain well. In the biliary form toxæmia is the special danger and we have no means of arresting the progress of the disease. In the alcoholic form it is too late, as a rule, to do much after symptoms have occurred. In a few cases an attack of jaundice or hæmatemesis may prove the salvation of the patient, who may afterward take to a temperate life. The diet should be very simple (largely milk and milk foods, simple carbohydrates and fruits) and large amounts of water taken to aid elimination. The bowels should be kept open, for which the use of the salines is generally best. An occasional course of potassium iodide may be given. With the advent of ascites the critical stage is reached. Restriction of fluid intake and free purgation may relieve a small exudate, rarely a large one, and it is best to tap early. In the syphilitic cirrhosis much more can be done, and a majority of the cases of cure after ascites are of this variety. Iodide of potassium in moderate doses, 15 to 30 drops of the saturated solution, and mercury save a number of cases. The diagnosis may be reached only after removal of the fluid, but in every case with a suspicion of syphilis, or with irregularity of the liver this treatment should be tried.

(a) *Tapping.*—When the ascites increases it is better to tap early. As Hale White remarks, a patient with portal cirrhosis alone who is tapped rarely recovers, but there are instances in which early and repeated para-

centesis is followed by cure. Accidents are rare; hæmorrhage, acute peritonitis, or erysipelas at the point of puncture occasionally follow; collapse may occur during the operation, to guard against which Mead advised the use of the abdominal binder. Continuous drainage with Southey's tubes has no special advantages. (b) *Laparotomy*, with complete removal of the fluid, and freshening or rubbing the peritoneal surfaces, to stimulate the formation of adhesions. (c) *Omentopexy*, the stitching of the omentum to the abdominal wall, and the establishment of collateral circulation in this way between the portal and the systemic vessels. This operation is sometimes successful. In 224 cases there were 84 deaths and 129 recoveries; 11 cases doubtful. Among the 129 successful cases, in 25 the ascites recurred; 70 appeared to have completely recovered. (d) *Fistula of Eck*. The porto-caval anastomosis has been performed once in man in cirrhosis of the liver (Widal, *La Semaine Médicale*, 1903). The patient lived for three months. (e) *Auto-drainage*, in which the fluid is drained into the subcutaneous tissues.

VIII. ABSCESS OF THE LIVER

Etiology.—Suppuration within the liver, either in the parenchyma or in the blood or bile-passages, occurs under the following conditions:
